Neonatal hyperbilirubinemia in late preterm newborns is more prevalent, more pronounced, and more protracted in nature than it is in their term counterparts. Jaundice was the most common cause of rehospitalization, and late preterm infants were more likely to be rehospitalized for jaundice than term infants (4.5% versus 1.2% in term infants).[20] Hyperbilirubinemia is a significant problem in these infants, as shown by their overrepresentation in the kernicterus registery.[6] The large size of late preterm infants may fool practitioners into complacency for treating them as term infants; however, close follow-up and monitoring for feeding difficulties should be mandated to prevent kernicterus in this vulnerable group.

Immunity and Infection

It has been shown that late preterm infants undergo workups for sepsis more often than term infants (36.7% versus 12.6%; odds ratio 3.97, 95% CI 1.82 to 9.21, $P = .00015$), and receive antibiotics more often and for a longer duration (7-day course in 30% versus 17% of term infants).[73] Another study found that the likelihood of having a workup for sepsis increased with decreasing gestational age; 33% had workups for sepsis at 34 weeks compared with 12% at 39 weeks of gestational age ($P \leq .01$), of which only 0.4% of these infants had culture-proven sepsis.[47] Late preterm infants undergo workups more often for sepsis either as a part of a protocol after admission to the NICU or because of clinical manifestations of RDS, cold stress, and hypoglycemia, which may appear to be signs of sepsis to the physician.

HOSPITALIZATIONS AND REHOSPITALIZATIONS AFTER DISCHARGE

Late preterm infants are more likely to require intensive care and are admitted to the NICU more often than term infants. Admission rates vary based on the policies of individual institutions and hospitals; some routinely admit all infants less than 35 weeks of gestation to the NICU, and others do so only if there is a need. One large population-based study found that 88% of infants born at 34 weeks' gestation, 12% born at 37 weeks' gestation, and 2.6% born at 38 to 40 weeks' gestation were admitted to an NICU.[17] Another study found that 97%, 53%, and 32% of infants of 34 weeks, 35 weeks, and 36 weeks of gestation required NICU admissions,[69] whereas one study found much lower rates of 5%, 2%, and 1.1% in infants of 34 weeks, 35 weeks, and 36 weeks of gestation, but this was still significantly higher than admissions of infants of 39 weeks of gestation (0.5%).[47] Duration of hospital stay is also inversely proportional to gestational age, with late preterm infants requiring much longer hospital stays (6 to 11 days, 4 to 6 days, and 3 to 4 days in 34-week, 35-week, 36-week infants).* The most common reasons for admission include jaundice, RDS, dehydration and poor feeding, hypoglycemia, and temperature instability.[69,73]

Aside from the greater need for specialized care, and prolonged initial hospital stay, late preterm infants are also at risk for rehospitalization after discharge from the hospital.[19,20,63,64] Looking at a large population-based cohort in a managed care organization, Escobar and colleagues[19-21] found that late preterm infants (4.4%) had a higher rate of rehospitalization than term infants (2%), and the rate was higher than for infants less than 34 weeks' gestational age (3%). They also found that infants of 34 weeks and 36 weeks of gestation never admitted to the NICU and infants with NICU stays less than 24 hours had nearly 3 times and 1.3 times the risk of readmission than term infants, which indicates that clinicians may be treating these immature infants based on their weight and failing to identify all of the risk factors.

---

*References 20, 24, 35, 47, 53, 69.

Another large population-based study from Massachusetts reported the readmission rate to be 4.8%, similar to the Escobar study.[64] Early discharge (<2 days) from the hospital is also a risk factor. Tomashek and coworkers,[68] looking at late preterm infants born vaginally and discharged early from the hospital in Massachusetts during 1998-2002, found that 4.3% of late preterm infants and 2.7% of term infants either were readmitted or had an observational hospital stay. They were twice as likely to be readmitted as term infants; breast-fed late preterm infants were also two times more likely to be readmitted. A possible explanation could be that infants were discharged home before proper milk supply set in.

The most common reasons cited for readmission include hyperbilirubinemia (63% to 71%), feeding difficulties (16%), and suspected sepsis (6% to 20%).[20,21,64,68] The infants requiring rehospitalization were more likely to be firstborn, be breast-fed at discharge, have labor and delivery complications, be a recipient of a public insurance at delivery, or be of Asian/Pacific islander descent.[64] Given that late preterm infants are at a much higher risk for rehospitalization, protocols need to be designed for closer monitoring of breast-fed infants of new first-time mothers and infants at risk for jaundice, especially of Asian descent, avoiding early discharge until proper feeding has been established, and ensuring early follow-up after hospital discharge.

Economic Impact

The Institute of Medicine estimated that every preterm birth costs \$51,600 with a total impact of \$26 billion in 2005.[5] Late preterm infants are responsible for a significant share of this burden, constituting 72% of all preterm births.[17,18,21,34,69] It is estimated that a relative increase in direct costs for late preterm infants is 2.9 times that of a term infant, resulting in a cost increase of \$2630 per infant ($P < .0004$).[73] A large population-based study over a 1-year period (1996) in California found that hospital costs for an infant of 34 weeks' gestation were \$7200; of 35 weeks, \$4200; and of 36 weeks, \$2600, compared with \$1100 for an infant of 38 weeks' gestation. Delaying delivery by just 1 week from 34 to 35 weeks reduced the cost by 42% and from 35 to 36 weeks by 38%.[24] A similar California cohort for 2000 showed hospital costs of \$7081 for infants of 33 to 36 weeks' gestation.[62]

Another large cohort from a Dallas hospital over an 18-year study period found that the average hospitalization costs for late preterm infants were \$3098, and for 39-week term infants were \$1258 (\$6094 for infants of 34 weeks; \$3519, for 35 weeks; and \$2019, for 36 weeks).[47] Similarly, Phibbs and associates[53] looked at all births between 24 weeks and 37 weeks of gestation from 1998-2000 in California, and found that the cost reduction for delaying preterm delivery by 1 week from 34 to 35 weeks was \$4528, and by 3 weeks to 37 weeks was \$8508. In a study by Gilbert and associates,[24] the average cost for each infant of 25 weeks' and 35 weeks' gestation was approximately \$202,700 and \$4200, but when the total cost for all infants in each gestation group was calculated, the cost for 35-week infants was \$41.1 million, and the cost for 25-week infants was \$38.9 million. Although extremely preterm infants are very expensive to treat, the overall cost of treating the cohort of late preterm infants is similar because of the large number of infants treated. Gilbert and associates[24] also estimated the excess cost of medical care for the late preterm infants for that year in this cohort compared with the cost of treating the term infants was nearly \$50 million, but it is very hard to separate preventable late preterm births from unpreventable births—hence the difficulty in estimating the excess cost attributable to iatrogenic and preventable preterm birth.[24]

Although we do not have estimates for late preterm infants in particular, the Institute of Medicine report estimates that postdischarge services for preterm infants, inclusive of early intervention services, cost an estimated \$611 million (\$1200 per infant), whereas special education services associated with a higher prevalence of four disabling conditions, including cerebral palsy, mental retardation, vision impairment, and hearing loss, among premature infants added \$1.1 billion (\$2200 per preterm infant). Lost household and labor market productivity associated with those disabling conditions contributed \$5.7 billion (\$11,200 per preterm infant).[5] Because of their high numbers, reducing late preterm births or delaying them by even 1 week can have a significant economic impact.

Long-Term Outcomes and Societal Costs

Although it is well known that very preterm infants are at a higher risk of psychomotor, behavioral, cognitive, and other developmental disabilities, there are few studies of long-term outcomes in late preterm infants. A large Swedish population-based study including 903,402 children (32,945 late preterm infants) who were born alive without any congenital anomalies from 1967-1983 and followed through adulthood until 2003 found a higher incidence of cerebral palsy (relative risk 2.7, 95% CI 2.2 to 3.3, $P < .001$), mental retardation (relative risk 1.6, 95% CI 1.4 to 1.8, $P < .001$), disorders of psychological development, behavior and emotional disturbances, other major disabilities (blindness, low vision, hearing loss, and epilepsy), and medical disability affecting working capacity.[50] Societal costs are hard to estimate. Another Swedish study by Lindstrom and colleagues[41] estimated that among a cohort of approximately 500,000 adults in their 20s, moderately preterm infants of 33 to 36 weeks' gestation and early term infants received increased disability assistance/allowance and were less likely to attain university or postsecondary education. Of neurologically disabled individuals in this cohort, 74% were born between 33 and 38 weeks of gestation.

Chyi and colleagues,[10] using the Early Childhood Longitudinal Study–Kindergarten Cohort (ECLS-K), compared learning difficulties among moderately preterm (32 to 33 weeks of gestation), late preterm (34 to 36 weeks of gestation), and full-term infants using direct child assessment tests and teacher academic rating scale scores. They found that late preterm infants on direct child assessment tests scored lower than full-term infants for reading but not math in kindergarten and first grade. For teacher academic rating scales scores, late preterm infants scored lower in reading in kindergarten, first grade, and fifth grade, and scored lower in math assessments in kindergarten and first grade. Late preterm infants also showed an increased need for individualized educational programs and special education in kindergarten and first grade. In regression analysis, late preterm infants had a 24% increased adjusted odds ratio for below-average reading in the first grade, and were 1.3 times more likely than full-term infants to have below-average reading across all grade levels in the teacher assessment scores. The reason for not seeing a difference in the later grades for math scores was probably due to a high number of infants lost to follow-up toward the later grades (34% at fifth grade) and the higher number of disabilities seen in the lost-to-follow-up group.[10]

The study by Chyi and colleagues[10] shows that late preterm birth has a significant impact on the growing and immature preterm brain; being born only a couple of weeks before term gestation is not so benign and has a lifelong detrimental impact with significant costs to family and society. These retrospective reports in no way confirm causality. It is unclear if the neurologic injury resulted from or predated the event that caused the late preterm birth. The hypotheses generated by these reports need further testing: Are late preterm infants at higher risk for short-term and long-term morbidity and death than their term counterparts, and if so, why?

MANAGEMENT

Late preterm infants are a special population that needs closer monitoring and care. A good starting point to address the problem of providing this care would be the availability of reliable data about short-term and long-term outcomes of late preterm infants and documentation of serious morbidity that could dispel the myth of the "transient" nature of late preterm problems. There is an urgent need to implement guidelines for the management of late preterm infants. A comprehensive guide for management of late preterm infants was published more recently and is summarized in Box 34-2.[18]

Admission

It is recommended that infants of less than 35 weeks of gestation or weighing less than 2300 g should be admitted to an area where they can be monitored closely for stability. Transfer to the mother's room or regular "term" nursery environment should be considered only when they show stability of temperature, vital signs, blood glucose, and oral feeding. These infants should have a physical examination on admission and discharge, with determination of accurate gestational age on admission examination.

We recommend using the obstetric estimate of gestational age if it is based on a first-trimester ultrasound. If there is a discrepancy (e.g. > 2 weeks) between the gestational ages based on the obstetric estimate and the newborn examination, the use of gestational age based on the newborn examination is preferred. Vital signs and oxygen saturation should be performed on admission and monitored with appropriate frequency thereafter. Transfer to an NICU or tertiary care center should be considered if fraction of inspired oxygen (F_{IO_2}) exceeds 0.4. A feeding plan should be developed, and formal evaluation of breast feeding should be done at least twice daily after birth with documentation in the record by caregivers trained in breast feeding. Serum glucose screening should be performed per existing protocols for infants at high risk of hypoglycemia—infants who are small for gestational age, large for gestational age, and infants of diabetic mothers.

BOX 34–2 Admission and Discharge Criteria Management of Late Preterm Infants

ADMISSION CRITERIA

- Admit all infants <35 weeks' gestational age or <2300 g birthweight
- Infants should not to be sent to their mother's rooms in the first 24 hours until stable, unless arrangements can be made to provide transitional care and close monitoring in the mother's room

HOSPITAL MANAGEMENT

- Physical examination on admission and discharge
- Determination of accurate gestational age on admission examination
- Vital signs and pulse oximeter check on admission, followed by vital signs every 3-4 hours in the first 24 hours, and every shift thereafter
- Caution against use of oxyhoods with high F_{IO_2}; consider transfer to NICU/tertiary care center if F_{IO_2} exceeds 0.4
- Feeding plan should be developed; formal evaluation of breast feeding and documentation in the record by caregivers trained in breast feeding at least twice daily after birth
- Serum glucose screening per existing protocols for infants at high risk of hypoglycemia

DISCHARGE CRITERIA

- Discharge should not be considered before 48 hours after birth
- Vital signs should be normal for 12 hours before discharge
- Passage of one stool spontaneously
- Adequate urine output
- Successful feeding for 24 hours: ability to coordinate sucking, swallowing, and breathing while feeding
- If weight loss $>7\%$ in 48 hours, consider further assessment before discharge
- Risk assessment plan for jaundice for infants discharged within 72 hours of birth
- No evidence of active bleeding at circumcision site for at least 2 hours
- Initial hepatitis B vaccine has been given or an appointment scheduled for its administration
- Metabolic and genetic screening tests performed in accordance with local or hospital requirements
- Passed car seat safety test
- Hearing assessment has been performed and results documented in the medical record; follow-up if necessary has been arranged
- Family, environmental, and social risk factors have been assessed; when risk factors are present, discharge should be delayed until a plan for future care has been generated
- Identification of a physician with a follow-up visit arranged for 24-48 hours
- Give mother and caregivers training and competency in care of the infant

NICU, neonatal intensive care unit.

Discharge Criteria

Discharge should not be considered before 48 hours after birth. Vital signs should be normal for 12 hours preceding discharge: respiratory rate, less than 60 breaths/min; heart rate, 100 to 160 beats/min; and axillary temperature, 36.5°C to 37.4°C in an open crib with appropriate clothing. There should be documentation of passage of at least one stool spontaneously, with adequate urine output, and 24 hours of successful feeding; adequate oral feeding should be present with confirmation of coordination of sucking, swallowing, and breathing while feeding. If weight loss is greater than 7% in 48 hours, further assessment should be considered before discharge.

There should be a risk assessment plan for jaundice in infants discharged within 72 hours of birth; predischarge bilirubin check (serum or transcutaneous) should be done before discharge. A transcutaneous bilirubin of greater than 12 mg should be confirmed with a serum bilirubin, and bilirubin nomograms should be used to determine the risk and need for follow-up or treatment. There should be no evidence of active bleeding at the circumcision site for at least 2 hours. The initial hepatitis B vaccine should have been given or an appointment scheduled for its administration, and the metabolic and genetic screening tests should have been performed in accordance with local or hospital requirements. A car seat safety test and a hearing assessment should be performed, and results should be documented in the medical record.

When social risk factors are present, discharge should be delayed until a plan for future care has been generated. A follow-up visit with a physician should be arranged for 24 to 48 hours after discharge. The mother and caregivers should have received training and demonstrated competency in the following activities: knowledge of urine/stool frequency, umbilical cord and skin care, identification of common signs and symptoms of illness, specific instructions concerning jaundice, specific instructions regarding sleeping patterns and positions, instructions on thermometer use, and instruction regarding responses to an emergency.

CHAPTER 35

Nutrition and Metabolism in the High-Risk Neonate

Brenda Poindexter and Scott Denne

Current recommendations for the provision of parenteral and enteral nutrition to the infant born prematurely are based on the goal of approximating the rate and composition of weight gain of a normal fetus at the same postmenstrual age. For a number of reasons, this goal is seldom achieved and postnatal growth failure remains a nearly universal complication of extreme prematurity. Infants who experience one or more major morbidity such as bronchopulmonary dysplasia, necrotizing enterocolitis, or late-onset sepsis in the neonatal period demonstrate slower growth than their counterparts who do not experience these conditions. Of particular concern is the association between suboptimal postnatal growth and poor neurodevelopmental outcomes at 18 to 22 months of corrected age.

Ehrenkranz and colleagues evaluated the association between growth in the neonatal intensive care unit and neurodevelopmental and growth outcomes in infants with extremely low birthweight (ELBW) in a multicenter cohort study from the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network.[40] Infants were divided into quartiles based on in-hospital growth velocity; infants in the lowest quartile had an average weight gain of 12 g/kg per day and those in the highest quartile gained 21 g/kg per day on average. At 18 to 22 months of corrected age, as the rate of in-hospital weight gain increased between the lowest and highest quartile, the incidence of cerebral palsy, Bayley Mental Developmental Index less than 70 and Psychomotor Developmental Index less than 70, abnormal neurologic examination, neurodevelopmental impairment, and the need for rehospitalization decreased significantly. Similar findings were also observed as the rate of head circumference growth increased. As evidence continues to accumulate that early nutritional inadequacies have long-term consequences, optimizing provision of both parenteral and enteral nutrition to high-risk neonates is crucial to ensure the best possible outcomes.

INCIDENCE OF POSTNATAL GROWTH FAILURE

At the time of birth, approximately 20% of infants with very low birthweight (VLBW) are small for gestational age (defined as weight less than the 10th percentile).[43] After a stay in the neonatal intensive care unit, however, the vast majority of these infants will have experienced poor growth and weigh less than the 10th percentile at 36 weeks' postmenstrual age. The NICHD Neonatal Research Network has published growth outcomes of infants with VLBW over the past decade. Among infants with VLBW born at centers participating in the Neonatal Research Network between 1995 and 1996, 97% were found to have growth failure at 36 weeks of postmenstrual age.[66] In a more recent cohort of infants (1997-2002), the overall incidence of postnatal growth failure was modestly improved, 91%,[43] possibly reflecting widespread use of early parenteral nutrition at most neonatal intensive care units as well as a decline in the use of postnatal corticosteroids. Other large cohort studies have also documented a high rate of extrauterine growth restriction at the time of hospital discharge. Data from the Pediatrix Medical Group, Inc., found the incidence of extrauterine growth restriction to be 28%, 34%, and 16% for weight, length, and head circumference, respectively, in a large cohort of premature (23 to 34 weeks' estimated gestational age) infants at the time of hospital discharge.[26] In this same cohort, the incidence of extrauterine growth restriction increased with decreasing estimated gestational age and birthweight.

Among potential causes of postnatal growth failure are significant protein and caloric deficits that occur in the early neonatal period that are difficult to recoup in extremely premature infants.[41] Early deficiencies in protein are a particularly important contributor to the poor growth outcomes observed in this population.[10,76] Consequently, provision of nutrition to preserve endogenous protein stores and to promote optimal rates of protein accretion is necessary to optimize growth in premature infants.

PART 1

Parenteral Nutrition

The nutritional support of infants with ELBW, especially in early postnatal life, is almost entirely dependent on the parenteral route. The extremely premature neonate is born with glucose stores of only 200 kcal and loses 1% of body protein per day when provided with intravenous glucose alone. Extreme prematurity should be viewed as a nutritional emergency and parenteral nutrition should be provided as soon as possible after birth.

INTRAVENOUS PROTEIN AND AMINO ACID REQUIREMENTS

Duplicating rates of in utero protein accretion is a difficult clinical challenge. Failure to provide adequate protein, either in quantity or in quality, can significantly impact the long-term outcome of extremely premature infants. A variety of methods have been used to quantitate protein requirements in human infants: fetal accretion rates, nitrogen balance studies, plasma amino acid concentrations, and stable isotope studies investigating the kinetics of labeled essential amino acids. Clearly, the gold standard needs to be that which safely optimizes growth and neurodevelopment.

Normal human fetal development is characterized by rapid rates of growth and accretion of protein. In fact, the greatest rate of relative protein gain throughout life occurs before birth. At 26 weeks' gestation, the human fetus gains approximately 1.8 to 2.2 g of body protein per day, with the placenta supplying about 3.5 g/kg per day of amino acids to the developing fetus. The placental supply of amino acids to the fetus is in excess of that needed for accretion of protein. The extra amino acids are oxidized by the fetus and contribute significantly to fetal energy production. High rates of protein turnover are required to support protein synthesis, tissue remodeling, and growth. Analysis of fetal body composition indicates that at 28 weeks' gestation, the fetus accretes approximately 350 mg of nitrogen per kilogram per day (protein values in milligrams can be found by multiplying nitrogen values in milligrams by 6.25). At term, nitrogen accretion declines to about 150 mg/kg per day. Postnatal nitrogen loss decreases with gestational age as well, from 180 mg/kg per day at 27 to 28 weeks to 120 mg/kg per day for a full-term infant.[60] Rates of protein catabolism have also been measured in a series of studies employing stable isotopes across a wide range of gestational ages. In the absence of intravenous amino acids, protein losses in extremely premature infants are approximately twofold higher than that in term infants.[28,36,81] Consequently, protein requirements extrapolated from fetal nitrogen accretion rates and postnatal losses have been estimated at 2.5 to 3.5 g/kg per day for premature infants and 1.9 to 2.5 g/kg per day for term infants. Because protein losses are inversely related to gestational age, protein requirements are likely to be even higher in extremely premature infants.

In contrast to the high rate of protein gain in utero, extremely premature infants lose approximately 1.2 g/kg of protein each day that they receive glucose alone.[36] This corresponds to a daily loss of 1% to 2% of total endogenous body protein stores. In just a few days, the gap between what would have been protein accretion in utero and what has become postnatal protein loss widens considerably, illustrating the extent of protein deficit that can quickly accrue in the absence of intravenous amino acids. As discussed later, provision of as little as 1 g/kg of amino acids can offset this disparity and achieve a net protein balance close to zero, whereas delivery of 3 g/kg per day of amino acids results in net protein gain that approximates that of the reference fetus (Fig. 35-1).

EVIDENCE SUPPORTING EARLY NUTRITIONAL SUPPORT WITH PARENTERAL AMINO ACIDS

In the past, it was not uncommon for premature infants to receive intravenous glucose alone for the first several days of life. Consequently, most of the early studies compared a particular amino acid dose with glucose alone.[6] In several different studies, nitrogen balance was measured in premature infants receiving glucose alone and in response to varying intake of amino acids (1.15 to 2.5 g/kg per day). Despite differences in the study populations and in the composition of the amino acid solutions (some studies included cysteine supplementation; others did not), all studies demonstrated positive nitrogen balance in response to parenteral amino acids.* Positive nitrogen balance was found despite low total

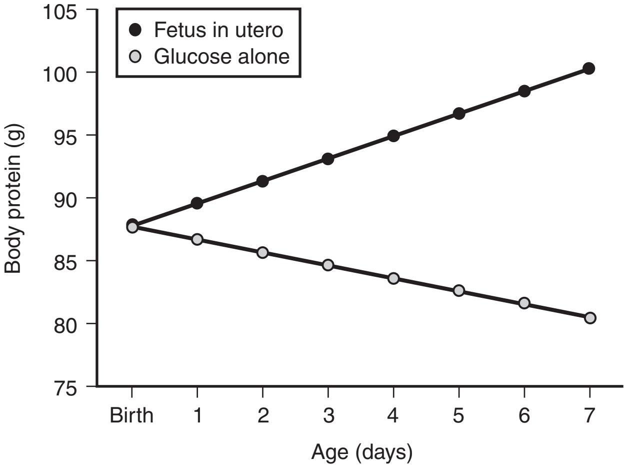

Figure 35–1. Change in body protein over the first week of postnatal life for a theoretical 1000-g birthweight, 26 weeks' gestation infant provided with 1 and 3 g/kg/d of intravenous amino acids.[105,113] Rate of in utero protein gain for the reference fetus[120] and extrapolated rates of protein loss for glucose alone[36] are shown for comparison.

caloric intake (approximately 50 kcal/kg per day). Consequently, the initial goal of limiting catabolism and preserving endogenous protein stores in premature infants can be accomplished with provision of as little as 1 to 1.5 g/kg per day of intravenous amino acids, even when total caloric intake is low.

Stable isotope techniques have also been used to evaluate the effect of amino acids on protein metabolism in premature infants. In these studies, stable isotope tracers of one or more essential amino acids are used to reflect whole body protein kinetics. Rivera and colleagues found that administration of 1.5 g/kg per day of amino acids (Aminosyn-PF with cysteine added) beginning on the first day of life improved protein balance as a result of increased protein synthesis (as reflected by leucine kinetics).[85] Using similar techniques, van den Akker and colleagues demonstrated that protein anabolism produced by administration of early amino acids is accomplished through an increase in protein synthesis and not from a decrease in proteolysis (protein breakdown).[112]

Other investigators have assessed the safety and efficacy of different doses of amino acids. Thureen and colleagues conducted a randomized trial of low (1 g/kg per day) versus high (3 g/kg per day) amino acid intake in infants with ELBW immediately after birth.[105] The higher amino acid intake produced significantly greater protein accretion. In an open-label trial, te Braake and colleagues randomized infants with VLBW to two different parenteral amino acid regimens.[104] Infants in the intervention group received 2.4 g/kg per day of amino acids starting immediately after birth. Infants in the control group received glucose alone on the first day of life, with a stepwise increase in amino acid intake thereafter (1.2 g/kg on day 2 and 2.4 g/kg on days 3 and 4). Infants who received amino acids on the first day of life had positive nitrogen balance without any major adverse effects, whereas infants in the control group were in negative nitrogen balance on day 2. Ibrahim and colleagues evaluated an even higher initial dose of intravenous amino acids, randomizing premature infants with VLBW to either 2 g/kg or 3.5 g/kg per day of intravenous amino acids on the first day of life. As in the studies discussed previously, the higher amino acid dose resulted in greater improvement in nitrogen balance without evidence of adverse effects.[56]

The safety of administration of early intravenous amino acids, particularly for premature infants, has been established in a variety of studies. Normal plasma amino acid concentrations have been reported using TrophAmine.[53] Rivera and colleagues studied infants with VLBW given amino acids in the first days of life and found no abnormal elevations of plasma amino acids, blood urea nitrogen (BUN), or ammonia.[86] Thureen and colleagues found that 3 g/kg per day of early amino acids appears to be as safe as 1 g/kg per day, based on BUN and plasma aminograms as indicators of acute amino acid toxicity.[77,105] Although most studies have not demonstrated any relationship between amino acid intake and BUN in the first days of life, two recent studies reported increased BUN levels in infants receiving higher amino acid intakes at 7 days of age.[15,25] As mentioned earlier, a significant proportion of the amino acids supplied to the developing fetus is oxidized and serves as a significant energy source for the fetus. Urea production is a byproduct of amino acid oxidation. In premature infants, rates of urea production are higher than in term neonates and adults, consistent with high rates of protein turnover and oxidation. Some investigators have even suggested that azotemia might be evidence of the effective use of amino acids as an energy supply rather than of protein intolerance, but this contention remains unproven.

Although the initial goal of providing intravenous amino acids to premature infants to limit catabolism and preserve endogenous protein stores can be accomplished even when total caloric intake is low, ultimately, both protein and energy must be supplied in quantities sufficient to support optimal growth. Protein quantity is the primary determinant of protein accretion, regardless of whether parenteral nutrition is used exclusively or as a bridge to full enteral feedings. In a series of studies, Zlotkin and colleagues evaluated the effect of intravenous energy and nitrogen intake on nitrogen retention.[121] At constant nitrogen intake, increasing nonprotein energy intake from 50 to 80 kcal/kg per day resulted in increased nitrogen retention and weight gain. However, at low energy intake (approximately 50 kcal/kg per day), increasing nitrogen intake from 494 to 655 mg/kg per day (3 to 4 g/kg of amino acids per day) had no effect on nitrogen retention or weight gain. However, at higher energy intakes (approximately 80 kcal/kg per day), the same increase in nitrogen intake resulted in a significant increase in the rate of both nitrogen retention and weight gain.

Many conditions and interventions commonly encountered in extremely premature infants are known to increase protein requirements. Underlying disease states such as sepsis or surgical stress increase catabolism and can negatively impact protein accretion. Medications such as systemic steroids, fentanyl, and insulin can also impact protein accretion. Dexamethasone increases protein catabolism by increasing protein oxidation and proteolysis, resulting in decreased accretion of protein.[114]

Although the upper limit of parenteral protein intake has yet to be defined, if the goal is to achieve fetal delivery rates, then reasonable estimates of requirements for infants born at the following estimated weeks of gestational age are 3.75 to 4 g/kg per day for 24 to 25 weeks, 3.5 g/kg per day for 27 to 28 weeks, 3.2 g/kg per day for 32 weeks, and 2.8 to 3 g/kg per day for term.[119]

Few studies have evaluated the longer term effects of early parenteral nutrition. In a single center observational study, Stephens and colleagues found an association between increased protein and energy intake in the first week of life and higher Bayley Mental Development Index scores and lower likelihood of length growth restriction at 18 months of corrected age.[103] Other observational studies have also found that a prospective strategy of initiating amino acids in the first 24 hours of life in infants weighing less than 1500 g at birth is associated with improved weight gain at 36 weeks.[110] Wilson and colleagues demonstrated in infants with VLBW that early aggressive parenteral nutrition combined with early enteral feeding reduced growth failure without an increased incidence of adverse clinical consequences or metabolic derangement.[117] The effect of early parenteral amino acids on growth at 36 weeks' postmenstrual age and growth and neurodevelopment at 18 months' corrected age was assessed from a cohort of infants with ELBW enrolled in the NICHD Neonatal Research Network multicenter randomized clinical trial of parenteral glutamine supplementation.[79]

Infants who received a minimum of 3 g/kg per day of intravenous amino acids in the first 5 days of life had improved growth outcomes (weight, length, and head circumference) at 36 weeks' postmenstrual age. The odds of having weight less than the 10th percentile for age at 36 weeks' postmenstrual age was approximately fourfold higher for infants who did not receive early amino acids. At 18 months of corrected age, no differences in neurodevelopment were observed between the groups, but male infants who did not receive early amino acids were twice as likely to have head circumference less than the 10th percentile.[83] Other investigators have also reported gender-specific differences in the effects of suboptimal nutrition.[30,72] This observation warrants further study.

INTRAVENOUS AMINO ACID MIXTURES

The first parenteral amino acid solutions used in neonates were hydrolysates of fibrin or casein. Concerns about these first-generation solutions included high concentrations of glycine, glutamate, and aspartate; the presence of unwanted peptides; and high acidity. Reports of hyperammonemia and acidosis in the early 1970s were associated with the use of these first-generation solutions in neonates. Although amino acid solutions have been significantly modified (see later), the perceived risks associated with the protein hydrolysates linger, contributing to the hesitancy by some clinicians to administer early parenteral amino acids.

The second generation of amino acid solutions consisted of crystalline amino acid mixtures (FreAmine III, Travasol, Aminosyn). The amino acid pattern of these mixtures reflects that of high-quality dietary proteins with large amounts of glycine and alanine, absence of glutamate and aspartate, and absence or poor solubility of tyrosine and cysteine.

The newest solutions include modifications of crystalline amino acids for use in pediatric patients. The currently available solutions include modifications of crystalline amino acids for use in pediatric and neonatal patients (Aminosyn-PF, Premasol, Primene, and TrophAmine; Table 35-1). TrophAmine was originally formulated to match plasma amino acid concentrations of healthy term, breast-fed infants; Premasol is identical in composition to TrophAmine. The composition of Primene, available outside of the United States, was derived from fetal and neonatal cord blood concentrations. Both TrophAmine and Premasol supply a mixture of *L*-tyrosine and *N*-acetyltyrosine. The bioavailability of *N*-acetyltyrosine, however, has been questioned. Neither Aminosyn-PF nor Primene supply a substantial amount of tyrosine. Cysteine is not supplied by most amino acid solutions because it is not stable for long periods of time in solution. However, cysteine hydrochloride can be added during the compounding process just before delivering the solution.

TABLE 35–1 Composition of Commercial Parenteral Amino Acid Solutions*

	Aminosyn-PF (Abbott)	Premasol (Baxter)	Primene (Baxter)	TrophAmine (B. Braun)
Histidine	312	480	380	480
Isoleucine	760	820	670	820
Leucine	1200	1400	1000	1400
Lysine	677	820	1100	820
Methionine	180	340	240	340
Phenylalanine	427	480	420	480
Threonine	512	420	370	420
Tryptophan	180	200	200	200
Valine	673	780	760	780
Alanine	698	540	800	540
Arginine	1227	1200	840	1200
Proline	812	680	300	680
Serine	495	380	400	380
Taurine	70	25	60	25

*Amino acid concentration in mg/dL; all amino acid mixtures shown are 10% solutions.
†Mixture of *L*-tyrosine and *N*-acetyltyrosine.

The ideal composition of intravenous amino acid mixtures is unknown. Although these solutions are widely used in the neonatal intensive care unit, normative data on plasma amino acid concentrations, particularly in infants with ELBW, has not been established. Whether the goal should be to match amino acid concentrations of term breast-fed infants or some other standard is not known. The ultimate goal is to achieve plasma amino acid concentrations in response to provision of parenteral nutrition that optimize both growth and neurodevelopment without toxicity. To optimize nutrition and growth, particularly in a premature infant, the requirements for specific amino acids need to be more precisely defined.

Several amino acids may be "conditionally essential" in premature infants. That is, the infant's ability to synthesize these amino acids de novo may be less than functional metabolic demands. Cysteine, tyrosine, and arginine are often considered conditionally essential amino acids for premature infants.

Tyrosine is not present in appreciable amounts in currently available amino acid solutions because of its low solubility. Snyderman found lower rates of weight gain, nitrogen retention, and plasma concentrations of tyrosine in premature infants given a tyrosine-deficient diet.[100] Tyrosine is synthesized endogenously from phenylalanine by phenylalanine hydroxylase. The activity of this enzyme in premature infants was thought to be inadequate for growth and nitrogen retention without tyrosine supplements. However, stable isotope studies have demonstrated active phenylalanine hydroxylation in very premature (26 weeks) and premature (32 weeks) infants.[27,36] Therefore, in the strictest sense, tyrosine is not an essential amino acid. However, it remains unclear whether enough tyrosine can be endogenously produced from phenylalanine in premature infants to support normal rates of protein accretion. *N*-acetyltyrosine, although currently added to TrophAmine, is not highly bioavailable. Nonetheless, several studies provide indirect evidence that *N*-acetyltyrosine improves protein accretion in preterm infants.[50,52] In addition, it is unclear whether premature infants can adequately catabolize tyrosine via oxidation by the enzymes tyrosine aminotransferase and 4-hydroxyphenylpyruvate dioxygenase. Inability to catabolize tyrosine can lead to transient neonatal tyrosinemia. Further studies are needed to better define premature infants' ability to catabolize tyrosine and to determine whether an alternative source of tyrosine is needed in parenteral amino acid solutions.

Cysteine may be a conditionally essential amino acid for premature infants, but is not contained in currently available amino acid solutions. Some studies have shown that fetal liver lacks the enzyme system to convert methionine into cysteine and infants on a cysteine-free diet demonstrate impaired growth and low plasma cysteine levels. Other studies have demonstrated that there is enough cystathionase in extrahepatic tissues of the fetus and premature infant to synthesize cysteine when an adequate amount of methionine is provided. Recent studies using stable isotope techniques have demonstrated active endogenous cysteine synthesis in infants with low birthweight.[93] Nevertheless, there is evidence to support that when cysteine hydrochloride supplements are added to parenteral nutrition, nitrogen retention is improved in premature infants.[101] Furthermore, the addition of cysteine hydrochloride improves the solubility of calcium and phosphorus in parenteral nutrition solutions. However, cysteine hydrochloride supplements can produce metabolic acidosis unless appropriately buffered with acetate.

Glutamine is one of the most abundant amino acids in both plasma and human milk, yet it is not supplied by currently available amino acid solutions because glutamine is unstable in aqueous solution. Glutamine is a major energy substrate for small intestinal mucosa, as proved by a high glutamine uptake from the lumen and from arterial blood during the newborn period in rats. Adding glutamine to the total parenteral nutrition (TPN) solutions of animals prevents atrophy of small intestinal mucosa and smooth muscle, improves the gut immune function, and reduces the incidence of fatty infiltration of the liver. Several studies suggest that parenteral glutamine supplementation is of benefit in selected populations of critically ill adults. However, the NICHD Neonatal Research Network conducted a multicenter, randomized clinical trial of parenteral glutamine supplementation and found that parenteral glutamine supplementation did not decrease mortality or the incidence of late-onset sepsis in infants with ELBW.[80] In addition, glutamine had no effect on tolerance of enteral feeds, necrotizing enterocolitis, or growth. Although parenteral glutamine seems to be well tolerated, routine use cannot be advocated at the current time given the lack of clinical efficacy. Future studies are needed to determine whether glutamine supplementation may have a role in select subsets of critically ill neonates.

Finally, taurine is synthesized endogenously from cysteine and is not part of structural protein. It is present in large concentrations in the retina and brain of the fetus, reaching a peak concentration at term gestation. When newborn nonhuman primates are fed taurine-deficient formula, growth is depressed, but this does not occur in human preterm infants, despite declining plasma and urine taurine levels. Nevertheless, there is some limited evidence that taurine supplementation might influence auditory brainstem evoked responses. Several pediatric intravenous amino acid solutions (TrophAmine, Primene, Aminosyn-PF) contain one to three times the amount of taurine found in breast milk.

Because none of the currently used amino acid solutions was designed specifically to meet the needs of extremely premature infants, future research efforts should be directed at designing a fourth generation of amino acid solutions to optimize amino acid nutrition provided to the most vulnerable infants.

INTRAVENOUS CARBOHYDRATE REQUIREMENTS

Because the supply of glucose to the fetus depends solely on maternal glucose, cord clamping at the time of birth requires that a number of events occur in order to maintain glucose homeostasis in the newborn. Fetal glucose use in utero matches umbilical glucose uptake, implying that glycogenolysis and gluconeogenesis are minimal in the fetus. Several factors promote glycogen deposition in utero: blunted pancreatic B-cell regulation of insulin secretion, high insulin receptor density, and relative glucagon resistance. In late gestation, the fetus begins to prepare for the transition to postnatal life by increasing hepatic glycogen stores and brown fat deposits. Hepatic glycogen synthesis increases in response to increases in adrenal corticosteroid production, also characteristic of late gestation. At the time of delivery, glucagon levels rise, and insulin levels fall. Higher levels of plasma catecholamines, both epinephrine and norepinephrine, directly stimulate increases in hepatic glucose output. The increased levels of epinephrine and glucagon stimulate lipolysis and the activity of phosphorylase, a key enzyme in glycolysis. The increased level of glucagon also results in increased activity of phosphoenolpyruvate carboxykinase, a rate-limiting enzyme in gluconeogenesis. The newborn must be able to initiate gluconeogenesis, because glycogen stores can sustain glucose production only for several hours after birth. All these changes act together to preserve glucose homeostasis after the infant's maternal source of glucose is removed with cord clamping.

Rates of glucose production and use have been quantified in term and preterm infants using stable isotope methodologies. Because neural tissue makes up a greater proportion of body weight, newborns have higher rates of glucose oxidation than adults, with glucose being the primary energy substrate for the brain. The rate of glucose production in term newborns is approximately 3 to 5 mg/kg per minute,[35] whereas extremely premature infants have an even higher rate of glucose production of approximately 8 to 9 mg/kg per minute.[54]

Because the premature infant has a higher rate of basal glucose use and factors such as hypothermia and respiratory distress that also increase glucose demand, early administration of parenteral glucose is critical. No definitive correlations between hypoglycemia and neurodevelopmental outcomes, particularly in infants with ELBW, have been established.[31,32] Nonetheless, it seems prudent to intervene for a plasma glucose level less than 40 mg/dL, particularly in a premature infant in the first few days of life.

Infants with ELBW are even more susceptible to hyperglycemia, particularly in the first few days of life when feedings are almost entirely parenteral. Historically, glucose intolerance in infants with ELBW was attributed to persistent endogenous hepatic glucose production in the face of increased exogenous supply, insufficient insulin production, or tissue insensitivity to insulin. However, Hertz and colleagues demonstrated that clinically stable infants with ELBW are able to suppress endogenous glucose production when given parenteral glucose. In this study, infants given a glucose infusion at a rate of 9 mg/kg per minute were able to suppress endogenous glucose production to nearly zero, demonstrating that there is no inherent immaturity in this process in extremely premature infants.[54] From a practical standpoint, understanding rates of endogenous glucose production is important to avoid iatrogenic hyperglycemia. In infants with ELBW, a reasonable approach is to start the glucose infusion rate at 6 mg/kg per minute, gradually advancing to 10 to 12 mg/kg per minute as long as hyperglycemia does not develop.

The definition of hyperglycemia also varies but is generally set at a plasma level greater than 150 mg/dL (8.3 mmol/L). Hyperglycemia is detected early through frequent glucose monitoring. Plasma glucose levels less than 200 mg/dL usually do not require intervention. Reducing the fluid needs and insensible water loss can reduce the glucose intake. Alternatively, a lower concentration of dextrose solution can be used, although solutions less than 2.5% should be avoided. Sterile water can be given enterally to decrease parenteral glucose intake without compromising total fluid intake. Lipid infusions have been shown to increase plasma glucose concentrations in premature infants when given at high infusion rates.

Although some have advocated the use of insulin to "promote growth," using insulin to facilitate tolerance of added parenteral calories,[13,29] other investigators found no net effect on protein anabolism in response to euglycemic hyperinsulinemia in infants with ELBW.[82] In addition, increasing glucose infusion beyond the capacity for glucose oxidation can result in lactic acidosis. An international randomized clinical trial was recently conducted to determine whether early insulin therapy would reduce hyperglycemia and affect outcomes in infants with VLBW.[9] The study was terminated early because of futility concerns and concluded there is little clinical benefit of early insulin administration. Although insulin may decrease the incidence of hyperglycemia, there was no difference in important outcomes such as mortality; early insulin may also increase the number of episodes of hypoglycemia. Consequently, the routine use of exogenous insulin cannot be recommended; administration of 0.05 to 0.1 U/kg per hour may be occasionally needed to treat hyperglycemia that is not responsive to efforts to decrease the glucose infusion rate.

INTRAVENOUS LIPID EMULSIONS

Intravenous lipids are important not only to prevent essential fatty acid deficiency but also as a significant source of nonprotein energy. Commercially available intravenous lipid solutions are made up of neutral triglycerides, egg yolk phospholipids to emulsify, and glycerol to adjust the tonicity. In the United States, intravenous lipid solutions are derived from soybean oil (Intralipid) or a combination of soybean oil and safflower oil (Liposyn II); these solutions contain long chain triglycerides. Some lipid preparations available in Europe include medium chain triglycerides (Medialipid) or a combination of olive oil and soybean oil (Clinoleic). Fish oil–based lipid emulsions (currently available in Europe and in the United States only under compassionate use protocols) can provide a direct source of very long chain omega-3 (Ω-3) fatty acids as docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA).[73] The compositions of parenteral lipid emulsions are listed in Table 35-2.

Lipid particles supplied by intravenous lipid solutions are similar in size to endogenously produced chylomicrons. Like chylomicrons, clearance of these lipid particles also depends on the activity of lipoprotein lipase. In premature infants less than 28 weeks' gestation, lipoprotein lipase activity and triglyceride clearance is reduced. Heparin theoretically releases lipoprotein lipase from the endothelium into the circulation, but there is no evidence that this increases lipid utilization in preterm infants. In addition, increased lipoprotein lipase activity may produce high levels of free fatty acids and be in excess of the clearance capacity of the premature infant. Consequently, the routine addition of heparin to lipid emulsions for this purpose (to stimulate lipolysis) is not recommended on the basis of currently available evidence.

In humans, linoleic and linolenic acids cannot be endogenously synthesized and are therefore essential fatty acids.

TABLE 35–2 Composition of Parenteral Lipid Emulsions

	Intralipid 20%	Liposyn-II 20%	Omegaven*
Oil			
Soybean	20	10	—
Safflower	—	10	—
Fish	—	—	10
Fats (%)			
Linoleic	50	65	0.1-0.7
α-Linolenic	9	4	<0.2
EPA	—	—	1.3-2.8
DHA	—	—	1.4-3.1
Arachidonic acid	—	—	0.1-0.4
Glycerol	2.3	2.5	2.5
Egg phospholipid	1.2	1.2	1.2
Phytosterols, mg/L	$348 + 33$	383	0

*Omegaven only available as 10% solution (10 g of lipid per 100 mL).
DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid.

Biochemical evidence of essential fatty acid deficiency can develop in preterm infants within 72 hours. Essential fatty acid deficiency can be avoided if a minimum of 0.5 to 1 g/kg per day of intravenous lipid is provided. To meet energy requirements, additional intravenous lipid is required in early postnatal life.

Intravenous lipids are available as 10%, 20%, and 30% emulsions. The 20% solutions are preferred because they have lower phospholipid-to-triglyceride ratios and liposomal content than the 10% solutions, resulting in lower plasma triglyceride, cholesterol, and phospholipid concentrations. A 30% solution has recently become available and may confer even more advantages, although comparative data are not yet available.

Carnitine facilitates transport of long chain fatty acids through the myocardial membrane and as such plays an important role in the oxidation of these long chain fatty acids. Premature infants receiving parenteral nutrition have low carnitine levels, but the clinical significance of this remains uncertain. A Cochrane review found no evidence to support the routine supplementation of parenterally fed neonates with carnitine.[17]

The early administration of intravenous lipids to preterm infants has been the subject of discussion and debate primarily centered on the acute metabolic effects of early intravenous lipids and potential adverse effects, such as chronic lung disease and bilirubin toxicity as a result of free fatty acids displacing bilirubin from albumin binding sites. A recent meta-analysis found no increase in chronic lung disease resulting from early lipid administration to premature infants.[98]

The rate of intravenous lipid infusion is important, and plasma lipid clearance is improved when intravenous lipid is given as a continuous infusion over 24 hours. Lipid infusion rates in excess of 0.25 g/kg per hour can be associated with decreases in oxygenation. Lipid infusion rates well under this value can be easily achieved in clinical practice if lipids are provided over 24 hours in an amount not exceeding 3 to 4 g/kg per day. This level of lipid intake is usually sufficient to supply the caloric needs of preterm infants (in combination with glucose) and is usually tolerated by premature infants. Triglyceride concentrations are most often used as an indication of lipid tolerance, and maintaining triglyceride concentrations below 150 to 200 mg/dL seems prudent.

Intravenous lipid emulsions may undergo lipid peroxidation, which may form organic free radicals and potentially initiate tissue injury. Light, especially phototherapy, may play some role in increasing lipid peroxidation in intravenous lipid emulsions. However, multivitamin preparations included in the intravenous solutions are a major contributor to a generation of peroxides, and lipid emulsions may have only a minor additive effect. Based on these studies, some clinicians protect intravenous lipid solutions from light, although the importance or efficacy of this practice is unclear.

ENERGY REQUIREMENTS IN THE PARENTERALLY FED INFANT

Preterm infants have very low energy reserves due to limited body fat and glycogen stores in the liver. Maintaining these limited energy stores requires an energy intake that approximates energy expenditure. Energy expenditure in premature infants is thought to be in the 50- to 60-kcal/kg per day range, although data in ventilated infants and infants with ELBW are limited. Thermal stress can substantially increase energy expenditure.[65] Conversely, activity contributes relatively little to energy expenditure in premature infants.[106]

The energy cost of growth in these infants has been estimated at about 5 kcal/g. To achieve the equivalent of the estimated third trimester in utero weight gain of 14 g/kg per day, theoretically, an additional energy intake of about 70 kcal/kg per day is necessary. However, several studies have shown that nitrogen accretion and growth rates similar to those achieved in utero can be sustained in preterm infants with a parenteral intake of 80 kcal/kg per day when an appropriate amount of nitrogen is provided.[24,121]

In the first few days after birth, a caloric intake of 50 to 60 kcal/kg per day approximates energy expenditure and therefore is a reasonable value for the maintenance requirements of premature infants. Additional calories, supplied by lipid and glucose, to provide 90 to 100 kcal/kg per day are required for growth and energy requirements, and may be even higher in infants with ELBW.[21] Parenteral energy requirements are less than those required for enteral nutrition because there is no energy lost in the stools.

INTRAVENOUS ELECTROLYTE, MINERAL, TRACE ELEMENT, AND VITAMIN REQUIREMENTS AND SUPPLEMENTATION

During the first week of life, sodium needs are low because of the expected free water diuresis. For infants with ELBW, addition of sodium to parenteral nutrition may not be necessary until about day 3 of life. It is necessary, however, to frequently measure sodium concentrations and water balance. After the initial diuresis, 2 to 4 mEq/kg per day is usually sufficient to maintain serum sodium in the normal range, but infants with ELBW sometimes require higher sodium intakes to compensate for larger renal sodium losses. Chloride requirements follow the same time course as sodium requirements and are approximately 2 to 4 mEq/kg per day. Once electrolytes are added to the parenteral nutrition solution, chloride intake should not be less than 1 mEq/kg per day, and all chloride should not be omitted when sodium bicarbonate or acetate is given to correct metabolic acidosis. Potassium requirements are also low in the first few days of life, and potassium should be omitted from parenteral solutions in infants with ELBW until renal function is clearly established. Potassium intakes of 2 to 3 mEq/kg per day are usually adequate to maintain normal serum potassium concentrations.

Parenteral nutrition solutions usually require the addition of anions, either as acetate or chloride. In general, excess anions should be provided as acetate to prevent hyperchloremic metabolic acidosis. Acetate can help avoid the metabolic acidosis associated with the addition of cysteine hydrochloride to parenteral nutrition solutions.

Supplying calcium and phosphorus in parenteral nutrition remains a significant clinical challenge because of limited solubility. It is currently not possible to supply enough calcium and phosphorus to support adequate bone mineralization in premature infants using currently available solutions. The solubility of calcium and phosphorus in parenteral nutrition solutions depends on temperature, amino acid concentration, glucose concentration, pH, type of calcium salt, sequence of addition of calcium and phosphorus to the solution, the calcium and phosphorus ratio, and the presence of lipid. Adding cysteine to parenteral nutrition lowers the pH, which improves calcium and phosphorus solubility. To achieve intrauterine rates of mineral accretion, the target intake should be 3.0 mmol/kg per day of calcium and 2.8 mmol/kg per day of phosphorus.[91] A calcium-to-phosphorus ratio of 1.7:1 by weight (1.3:1 by molar ratio) appears to be optimal for bone mineralization. Magnesium is also a necessary nutrient and should be supplied at 3 to 7.2 mg/kg per day.

Requirements for trace elements for premature infants are not well defined due to a lack of clinical studies that assess safety and efficacy. There is reasonable consensus that zinc should be included early in parenteral nutrition solutions (250 μg/kg per day for term and 400 μg/kg per day for premature infants). Other trace elements probably are not needed until after the first 2 weeks of life. Zinc and copper are available in the sulfate form and can be added separately to parenteral solutions. Several pediatric trace metal solutions contain zinc, copper, magnesium, and chromium, and vary in proportions; these are usually provided at 0.2 mL/kg per day. When trace metal solutions are used, additional zinc is usually needed to provide the recommended intake for preterm infants. Supplementation with selenium is suggested after 2 weeks of age, because premature infants can become selenium deficient after 2 weeks of exclusive parenteral nutrition. In infants with cholestasis, copper and manganese should be discontinued, and chromium and selenium should be used with caution and in smaller amounts with renal dysfunction. At present, parenteral iron is only recommended when preterm infants are exclusively nourished by parenteral solutions for the first 2 months of life.

Only one pediatric multivitamin preparation is currently available, and it is delivered with standard dosage of 2 mL/kg per day (maximum 5 mL). These dosages provide higher amounts of most of the B vitamins and lower amounts of vitamin A relative to the recommendations.

COMPLICATIONS OF PARENTERAL NUTRITION

The primary complications of parenteral nutrition are cholestasis and complications related to the intravenous line, although myriad complications were reported in the early days of parenteral nutrition use. Some complications (e.g., electrolyte imbalance, hypoglycemia, hyperglycemia, hypocalcemia, hypercalcemia, hypophosphatemia) can be prevented or corrected by manipulating the constituents of the infusate.

Hepatic dysfunction has long been recognized as an important complication of parenteral nutrition, manifested primarily as cholestatic jaundice. The initial lesion seen histologically is both intracellular and intracanalicular cholestasis, followed by portal inflammation and bile duct proliferation after several weeks of TPN. With prolonged administration, portal fibrosis and ultimately cirrhosis may develop.

The etiology of the parenteral nutrition-associated liver disease (PNALD) is unknown and is most likely multifactorial. The patients at greatest risk are critically ill premature infants who are susceptible to multiple insults, such as hypoxia, hemodynamic instability, and sepsis. A higher incidence of sepsis has been reported in infants affected by cholestasis.[78] The most frequently identified risk factors in parenteral nutrition-associated cholestasis are duration of parenteral nutrition, degree of immaturity, and delayed enteral feeding.[102] There is expanding evidence that even small-volume enteral feedings can reduce the incidence of cholestasis. Early studies of parenteral nutrition suggested a possible relationship between the quantity of amino acids and hepatic dysfunction. Studies using historical controls suggest that the newer amino acid solutions may result in less cholestasis.[50] The specific role of the quantity and composition of parenteral amino acids in the cause of cholestatic jaundice in premature infants remains unclear. Some investigators have hypothesized that fish oil lipid emulsions prevent steatosis, potentially through improved triglyceride clearance and anti-inflammatory properties.[4]

There have been several case reports in infants of improvement in PNALD with Omegaven.[18,37] Using historical controls as a comparison group, Gura and colleagues recently reported the safety and efficacy of fish oil–based lipid emulsions in 18 infants with short bowel syndrome in whom cholestasis also developed while receiving soybean emulsions.[49] This therapy is currently only available in the United States through compassionate use protocols. Data from randomized clinical trials are needed before a change in clinical practice is recommended to include Omegaven for the treatment of PNALD.

Indwelling venous catheters used to deliver TPN may be a source of complications. Both peripheral and central venous routes have been used to deliver TPN, but central delivery allows use of more concentrated formulations. The complications associated with venous catheters are usually the result of improper insertion or placement, bacterial or fungal colonization of the catheter, or vessel irritation or thrombosis.

Central venous catheters provide the advantage of a lower incidence of infiltration and an ability to deliver higher concentrations of infusate. However, they are not without potential disadvantages. Broviac catheters, in particular, are less than optimal for use in neonates because of the high incidence of infection and thrombosis associated with their use in this population. Long-line small-bore catheters that can be introduced percutaneously or surgically are available for use in the neonatal population. These catheters are composed of either silicone or polyurethane. The incidence of sepsis and thrombosis with either silicone or polyurethane lines is much lower than with the Broviac catheter. The incidence of line sepsis is not affected by whether these lines are placed percutaneously or surgically; however, there is a lower incidence of both infection and mechanical complication if these lines originate in a distal vein (scalp, arm, hand) rather than a proximal one. Pericardial tamponade, arguably the most serious complication, has been reported to occur with catheters made of both materials.[45]

Infection is probably the most frequent serious complication associated with peripheral and central catheters. The most commonly implicated bacterial agents are *Staphylococcus epidermidis* and *Staphylococcus aureus,* while *Candida albicans* and *Malassezia furfur* are the fungal agents most often implicated. The incidence of sepsis as a complication of TPN increases as gestational age decreases and the duration of TPN increases. The predisposition to develop sepsis in these infants probably is multifactorial. As noted earlier, the incidence of sepsis increases in infants in whom cholestasis has developed. There is also some evidence that the infusate per se may predispose these infants to nosocomial sepsis. An association has been reported between the use of intravenous lipid and coagulase-negative staphylococcal bacteremia. Similarly, there are numerous reports of *M. furfur* fungemia in infants receiving intravenous lipid. In both cases, the incidence increases when lipid is added to the infusate, suggesting that the lipid may provide a rich growth medium for skin flora that have colonized indwelling catheters.

PART 2

Enteral Nutrition

Achieving full and consistent enteral nutrition in infants with ELBW is particularly challenging, given the inherent problems of immature gut motility and function as well as the fear of necrotizing enterocolitis if feedings are advanced too quickly. This section reviews the basis of recommendations for the quantity and quality of macronutrients provided to premature infants in order to achieve growth similar to that of the fetus and to achieve optimal functional outcomes. In addition, evidence related to initiation and advancement of enteral feeds in premature infants is reviewed. Despite our lack of adequate and specific answers to some of these fundamental questions, it is important to develop a reasoned approach to nutritional support of the high-risk infant. Considerable flexibility must be incorporated into such guidelines. Clearly, the relative risks insofar as they are known must be carefully weighed against benefit. When sufficient data are not available to address the relative risk versus the benefit, clinical judgment must be used until adequate studies have been performed.

PROTEIN REQUIREMENTS IN THE ENTERALLY FED INFANT

Although most clinicians tend to think about enteral intake in terms of volume or kcal/kg per day, protein intake probably plays a more important role than energy in overall growth and development. The high incidence of postnatal growth failure in premature infants has been attributed to lack of adequate protein intake. Consequently, increased attention should be focused on quantifying enteral protein intake in the most premature infants in order to ensure optimal postnatal growth.

The protein content and composition of human milk changes throughout lactation; the concentration diminishes from about 2 g/dL at birth to about 1 g/dL for mature milk. Qualitative changes also occur during lactation, resulting in a whey-to-casein ratio of 80:20 at the beginning of lactation, changing to 55:45 in mature milk. Although the levels of casein, α-lactalbumin, albumin, and lysozyme remain constant, the levels of secretory immunoglobulin A and lactoferrin decrease. Because these different protein fractions have different amino acid profiles, the content of the individual amino acids also is affected.

Protein and energy requirements in relation to body weight determined by Ziegler using the factorial approach are listed in Table 35-3.[119] In the factorial approach, nutrient requirements are determined as the sum of the needs for growth plus needs for replacement of losses. The disadvantage of this method is that it cannot determine nutrient requirements for catch-up growth. Infants with lower birthweight have higher enteral protein requirements and a higher protein-to-energy ratio for optimal growth. Based on the factorial methods, infants who weigh less than 1200 g require approximately 4 g/kg per day of protein. As is discussed later, consistently delivering this amount of protein with enteral nutrition is a difficult task.

A report by the Life Sciences Research Office of the American Society for Nutritional Sciences recommends that formulas for term infants contain 1.7 to 3.4 g of protein per 100 kcal.[62] In practice, most commercially available standard term formulas in the United States contain between 2.1 and 2.4 g of protein per 100 kcal, which provides infants with 2 to 2.5 g/kg per day for the first month of life. Recent recommendations for protein intake from the European Society of Paediatric Gastroenterology and Nutrition (ESPGHAN) are 4 to 4.5 g/kg per day for infants up to 1000 g and 3.5 to 4 g/kg per day for infants weighing 1000 to 1800 g, which meets the needs of most very premature infants.[2] The ESPGHAN committee further commented that protein intake can be reduced toward discharge if the infant's growth pattern allows. The nutrition committee of the Canadian Paediatric Society recommends that infants weighing less than 1000 g receive 3.5 to 4 g/kg per day of protein.[19] However, some studies suggest that higher protein intakes in infants less than 1200 g may improve growth.[38]

Casein-predominant cow's milk formulas have the same whey-to-casein ratio as cow's milk (18:82). Whey-predominant formulas are made by adding bovine whey such that the whey-to-casein ratio becomes similar to that of human milk (60:40). Nevertheless, the protein and amino acid profile remains very different from that of human milk. Compared with human milk, whey-predominant formulas have higher levels of methionine, threonine, lysine, and branched amino acids. These differences in amino acids have not resulted in any apparent clinical consequences in either term or preterm infants. Currently, most commercially available formulas are whey predominant.

Protein requirements must be considered in the context of energy intake. Studies in preterm infants have documented that metabolic indexes, energy balance, and body composition of weight gain were better when feeding 115 kcal/kg per day and 3.6 g/kg per day of protein than when feeding either 115 kcal/kg per day with 2.24 g of protein or 149 kcal/kg per day with 3.5 g of protein.[62] Therefore, with a caloric intake of 115 to 120 kcal/kg per day, the enteral protein requirement of infants with VLBW is 3 to 3.6 g/kg per day. Most of these studies have been done in infants with birthweights between 1000 and 1500 g; the requirements of smaller neonates are uncertain.

Taurine is considered a conditionally essential amino acid in premature infants.[62] Taurine is synthesized endogenously from cysteine and is not part of structural protein. The highest concentrations are present in the retina and brain of the fetus, reaching a peak concentration at birth. Furthermore, taurine plays a role in liver function, growth, and fat absorption. Free taurine is found in human milk in higher concentrations than in maternal plasma, resulting in higher plasma and urine levels in breast-fed infants than in neonates fed unsupplemented formula. There is some evidence that taurine supplementation in infants weighing less than 1300 g allows development of more mature auditory brainstem evoked responses than in nonsupplemented infants at 37 weeks' postmenstrual age. On the other hand, no overt disease has been identified as a result of taurine deficiency in infants. Although it is not entirely clear whether supplemental taurine is necessary, almost all term and preterm formulas contain taurine at a level similar to that in breast milk.

TABLE 35–3 Protein and Energy Requirements of Premature Infants Determined by the Factorial Approach

Body Weight (g)	Protein (g/kg/d)	Energy (kcal/kg/d)	Protein/Energy (g/100 kcal)
500-700	4.0	105	3.8
700-900	4.0	108	3.7
900-1200	4.0	119	3.4
1200-1500	3.9	125	3.1
1500-1800	3.6	128	2.8
1800-2200	3.4	131	2.6

Derived from Ziegler EE: Protein requirements of very low birth weight infants, *J Pediatr Gastroenterol Nutr* 45(Suppl 3): 170, 2007.

CARBOHYDRATES IN THE ENTERALLY FED INFANT

Lactose is the predominant carbohydrate in human milk (6.2 to 7.2 g/dL) and supplies 40% to 50% of the caloric content. Lactose is hydrolyzed to glucose and galactose in the small intestine by β-galactosidase (lactase). Intestinal lactase activities in premature infants at 34 weeks' gestational age are approximately 30% of those of term infants.[61] Despite low lactase activities in premature infants, lactose is well tolerated by premature infants, and stable isotope data suggest efficient lactose digestion. However, most premature infant formulas include glucose polymers as a significant source of carbohydrate; these glucose polymers are digested by α-glucosidases, which achieve 70% of adult activity between 26 and 34 weeks' gestation. In addition, salivary and mammary amylases may contribute to glucose polymer digestion. Glucose polymers have increased caloric density without an increase in osmolality, and they may enhance gastric emptying.

LIPID REQUIREMENTS IN THE ENTERALLY FED INFANT

Fat provides the major source of energy for growing preterm infants. At birth, the digestive function of premature infants is not fully developed; preterm infants have decreased gut absorption of lipids because of low levels of pancreatic lipase, bile acids, and lingual lipase.[58,59] The fact that term and preterm infants absorb fat reasonably well is due to the development of alternative mechanisms for the digestion of dietary fat. One important mechanism is intragastric lipolysis, in which lingual and gastric lipases compensate for the low pancreatic lipase concentration. By 25 weeks' gestation, the serous glands of the tongue secrete lingual lipase, and gastric lipase is secreted from gastric glands. The fatty acids and monoglycerides resulting from intragastric lipolysis compensate for low bile acid concentration by emulsifying lipid mixtures. Lingual lipase can also penetrate the core of the human milk lipid globule and hydrolyze the triglyceride core without disrupting the globule membrane. Human milk provides another heterogeneous group of lipases—lipoprotein lipase, bile salt stimulated esterase, and nonactivated lipase—which continue in the intestine the lipolysis begun in the stomach.

Lipid digestion and absorption are also affected by the dietary fat composition. Fatty acid absorption increases with decreasing chain length and with the degree of unsaturation, meaning that medium chain triglycerides (MCTs) with chain lengths of 6 to 12 carbons are hydrolyzed more readily than long chain triglycerides (LCTs) and that fatty acids with more double bonds are absorbed more efficiently. In an attempt to increase the fat absorption of premature infants, the fat in commercial formulas contains relatively high levels of MCTs that can be absorbed without the need for lipase or bile salts. Standard commercial formulas for healthy term infants do not contain MCTs, and human milk typically contains 8% to 12% of fat as MCTs. Unlike LCTs, MCTs are readily hydrolyzed in the gut, and the released fatty acids are transported across the gut barrier without the need for bile acids. MCTs are then transported directly to the liver via the portal vein as nonesterified fatty acids. In addition, MCTs can enter mitochondria and be oxidized without the need for carnitine-mediated transport through mitochondrial membranes. However, inclusion of MCTs in infant formula remains controversial, because the available data do not support the assertion of improved fat absorption or improved growth in preterm infants.[19,62]

In human milk, fat is transported in globules consisting of a membrane composed of a polar mixture of proteins, phospholipids, triglycerides, cholesterol, glycoproteins, and enzymes surrounding a triglyceride core containing 98% of the fat in milk. The milk fat globules are among the largest structural components of milk, having a diameter of 4 mm in mature milk. The size of the globules increases with both length of lactation and length of gestation, with colostrum having smaller globules (especially in milk of women who deliver prematurely) than mature milk. As the total fat content of human milk increases postnatally, the percentage of cholesterol and phospholipids, both of which reside primarily in the milk fat globule membrane, decreases; in addition, the total phospholipid content decreases as lactation progresses. During the first weeks of lactation, preterm milk is also richer in membranous material compared with term or mature milk, resulting in a higher content of cholesterol, phospholipids, and very long-chain polyunsaturated fatty acids (LCPs) with chain lengths of 20 to 22 carbons (C20 to C22). Because these membranes act as emulsifiers that allow fat dispersion in an aqueous phase and limit lipolysis and oxidation, heat treatment or addition of fortifiers and supplements might disrupt this emulsion.

The milk fat content and nutritional value of human milk vary with time, and it does not always provide a complete source of nutrients for infants with VLBW. Its composition and energy content may vary in a pumping session and during subsequent changes throughout lactation. The total fat content of human milk at 3 days' lactation is approximately 2 g/dL; the fat content of mature milk is approximately 4 to 5 g/dL, with large individual variations possible.[14] The triglyceride of human milk is its most variable component, changing with gestational and postnatal age, time of day, duration of individual feeds, and maternal diet. Shifts in the dietary practices of a population result in changes in the fatty acid composition of human milk, because the type and amount of fat in the maternal diet affect the composition of milk fat. Maternal diets low in fat and high in carbohydrate lead to de novo synthesis of fatty acids within the mammary gland, which results in high concentrations of fatty acids of less than 16 carbons. Therefore, although the total amount of fat present in the milk remains in the normal range, the fat is more saturated. The protein content of breast milk decreases from about 2 to 3 g/dL in early lactation to 1 g/dL in mature milk. Although a more consistent final composition can be obtained by pooling pumped milk, even pooled breast milk cannot provide sufficient sodium, calcium, phosphorus, iron, vitamins B_2, B_6, C, D, and E, and folic acid to meet the needs of infants with VLBW. Studies have shown that such infants have higher rates of weight, length, and head circumference increases when fed fortified preterm human milk compared with those fed only mature human milk.[19]

Fatty acids represent about 85% of the triglycerides and therefore are the principal component of human milk lipids. Fatty acids in human milk are derived from the maternal diet, de novo synthesis by the mammary gland, and mobilization from fat stores. The fatty acid composition of human milk fat reflects the fatty acid composition of the maternal diet. The LCP composition of milk of women in the United States, Europe, and Africa is similar, with the exception of higher amounts of Ω-3 LCP in the milk of women whose diets contain a large quantity of fish. Medium-chain fatty acids (C8 to C10) do not normally account for more than 2% of the fats, even in milk from women who have delivered preterm. Arachidonic acid (AA; C20:4Ω-6) is the main LCP, and EPA (C20:5Ω-3) is found in small quantities in human milk.[14] DHA (C22:6Ω-3) is the main LCP of the Ω-3 series.

Fatty acid composition changes with progressing lactation and with gestational age. Most striking is the higher content of C8 to C14 fatty acids and of LCPs in preterm milk compared with that in term milk; the content of LCP decreases with increasing postnatal age. This may be an advantage for preterm infants, because shorter fatty acids are easier to digest, and LCPs are essential for brain and retinal development.

LCPs play an important role in the development of the infant's brain during the last trimester of pregnancy and during the first months of life.[109] The precursor C18 fatty acids for the Ω-6 and Ω-3 LCP series are linoleic acid (C18:2Ω-6) and α-linolenic acid (C18:3Ω-3). Both are recognized as essential dietary nutrients.[19] These are further elongated and desaturated to form other fatty acids, of which AA and DHA are essential for normal growth and development. Although the capacity for endogenous synthesis of LCP from precursor fatty acids in preterm and term infants was thought to be limited, stable isotope studies demonstrated that both term and preterm infants have the capacity to synthesize DHA and AA.[20,88] However, it remains unclear whether DHA and AA can be biosynthesized in quantities sufficient to meet the needs of these infants. In utero, LCPs are supplied to the fetus across the placenta. After birth, breast-fed infants receive sufficient preformed dietary LCP with human milk.

Although contained in human milk, until recently DHA and AA have been absent in most infant formulas. The effect of adding DHA and AA to term and preterm infant formulas has been an area of active investigation. Randomized, controlled trials in term infants have shown no effect on growth.[96] The effect of DHA and AA supplementation on visual acuity has been measured in a number of trials using a variety of methods; inconsistent and transient changes in visual acuity have been measured. Most trials have not measured a difference of supplementation on intellectual development. The Cochrane Review of the randomized, controlled trials does not support a clear benefit of added DHA and AA to the formulas,[96] and the Life Sciences Research Office (LRSO) Report on Infant Formulas did not recommend their addition.[68] However, based on the presence of DHA and AA in breast milk, the possibility of benefit, and no apparent adverse effects, most formula manufacturers have made available formulas with added DHA and AA.

Multiple randomized, controlled trials evaluating the addition of DHA and AA to preterm formulas have also been conducted.[44,57,62,68,97] Added DHA and AA has generally resulted in positive or neutral changes in growth, although there are some reports of a negative effect. Findings of improved visual acuity have been inconsistent. Formula supplemented with DHA and AA has produced positive changes in neurodevelopment measured in infancy in some, but not all studies. A meta-analysis demonstrated no improvement in visual acuity or neurodevelopment.[99] Because studies evaluating added DHA and AA have not been conclusive, the LSRO Report assessing nutrient requirements for preterm infant formulas recommended a minimum content of zero and a maximum concentration of DHA (0.35% of total fatty acids) and AA (0.6% of total fatty acids).[68] Currently, most formula manufacturers have elected to add DHA and AA to their premature formulas.

Cholesterol is a major component of cell membranes and a precursor in the synthesis of bile acids and some hormones. It is present in human milk in concentrations ranging from 10 to 15 mg/dL, although commercial formulas contain only trace amounts of cholesterol (approximately 1 to 2 mg/dL). The high cholesterol content of breast milk relative to formula is maintained at this level regardless of maternal diet. The groups that assessed the nutrient requirements for term and preterm infant formulas did not recommend addition of cholesterol to infant formulas because there was no convincing evidence of a beneficial short- or long-term effect of such an addition.[62,68] Furthermore, there is no evidence that added cholesterol would be equivalent to the cholesterol in a human milk globule.

Carnitine mediates the transport of long-chain fatty acids into mitochondria for oxidation and the removal of short-chain fatty acids that accumulate in mitochondria. Preterm infants may be at risk for carnitine deficiency, because they are heavily dependent on lipids as an energy source and because the plasma carnitine concentration of preterm infants is low, owing to limited endogenous synthetic ability.[62,68] In preterm infants not receiving supplemental carnitine, plasma and tissue carnitine levels decrease even in the presence of adequate precursor amino acid concentrations. Carnitine is found in human milk and is currently added to standard term and preterm formulas in amounts somewhat higher than in human milk.

Recommendations for fat content and composition of term infant formulas have been outlined in the comprehensive LSRO report; a minimum fat content of 4.4 g/100 kcal (40% of total energy) and a maximum of 6.4 g/100 kcal (57% of total energy) were recommended.[68] This report also recommends a minimum of 350 mg/100 kcal of linolenic acid (about 3% of calories) and a minimum of 77 mg/100 kcal of α-linolenic acid (about 0.7% of calories).

Infants with VLBW are susceptible to essential fatty acid deficiency because they are deprived of fat accretion during late pregnancy and must obtain their nutritional requirements from their diet. Recent recommendations for the fat content of preterm infant formulas are similar to those for term infant formula.[68] The recommended minimum fat content for preterm infant formula is 4.4 g/100 kcal (40% of total energy) and the maximum content is 5.7 g/100 kcal (52% of total energy). The recommended amounts of linoleic and α-linolenic acids in preterm infant formulas are the same as for term infant formulas.

ENERGY REQUIREMENTS IN THE ENTERALLY FED INFANT

Energy balance is a delicate equilibrium between energy intake and energy loss plus storage. Positive energy balance is achieved when exogenous metabolizable energy intake is greater than energy expenditure. Growth is then possible, with the excess energy stored as new tissue, usually fat. If exogenous energy intake is less than expenditure, energy balance is negative, and body energy stores must be mobilized to meet ongoing needs. During the acute phase of disease, the primary goal is not growth but avoidance of catabolism. This is difficult for infants with VLBW owing to their higher maintenance energy requirements, lower energy stores, and often reduced intake. The breakdown of estimated energy requirements for growing premature infants is listed in Table 35-4.

Energy is lost either by excretion or by expenditure. Energy excreted is lost primarily as fecal fat. In preterm infants receiving full enteral feeding, approximately 90% of energy intake is absorbed. Usual measurements of total energy expenditure include the energy used to maintain basal metabolic rate (BMR), as well as the postprandial increase in energy expenditure (diet-induced thermogenesis), physical activity, and energy for the synthesis of new tissue.[34,84] The BMR is the largest component of energy expenditure and includes energy requirements for basic cellular and tissue processes. In a critically ill patient, it also includes a “disease factor.” Little is known about this component in neonates, but it may contribute significantly in neonates with fever, sepsis, and chronic hypoxia. Because the BMR can be measured only after overnight fasting, the resting metabolic rate (RMR) has been accepted as an alternative. Absolute metabolic rate increases as the fetus grows. However, on a weight-normalized basis, the metabolic rate decreases. Thus the RMR of preterm infants on a per kilogram basis is higher than that of term infants, and the nutritional requirements on a per kilogram basis are correspondingly greater. The energy required for thermoregulation and activity can be minimized by keeping the infant in a thermoneutral environment and limiting stimulation. For example, energy requirements for thermoregulation are negligible under thermoneutral conditions, but routine nursing procedures can increase oxygen consumption or energy expenditure by as much as 10% in stable preterm infants. Both of these components may be of considerable magnitude in a critically ill infant. The estimated RMR of infants with low birthweights, including an irreducible amount of physical activity in a thermoneutral environment, is lower immediately after birth than later, and by 2 to 3 weeks of age, approximately 50 to 60 kcal/kg per day is needed to maintain weight. Energy expenditure ranging from 40 to greater than 70 kcal/kg per day has been reported in growing infants with VLBW.[84] In extremely preterm (26 weeks’ gestation) infants requiring mechanical ventilation at 3 to 5 weeks of age, energy expenditure rates of 90 kcal/kg per day have been measured.

TABLE 35–4 Estimated Energy Requirements for Growing Premature Infants

Factor	kcal/kg/d
Energy Expenditure	
Resting metabolic rate	40-60
Activity	0-5
Thermoregulation	0-5
Synthesis/energy cost of growth	15
Energy stored	20-30
Energy excreted	15
Total energy requirement (estimated)	90-120

The level of energy intake and diet composition determine the magnitude of diet-induced thermogenesis (DIT), which represents the energy required for transport, metabolism, and conversion of nutrients into stored energy. Estimates of DIT in enterally fed preterm infants vary considerably, but this component of expenditure is probably small.

Because neonates sleep 80% to 90% of the time, the energy expended in physical activity is a smaller component of energy expenditure in neonates compared with that in adults. It has been estimated that activity contributes approximately 10% to total energy expenditure in the neonatal period. One study[106] directly measured the energy expended in physical activity in stable preterm infants through the use of long-period respiratory calorimetry to measure total energy expenditure and a force platform to measure work output. The energy expended in physical activity was measured at 2.4 kcal/g per day, approximately 3.5% of total energy expenditure. Although the average magnitude of this component is small, it may have a significant impact on growth in irritable infants with poor responses to nursing care and interventions.

Total energy expenditure is affected by several factors, assuming a thermoneutral environment and minimal interference from nursing procedures. Increases in metabolic rate with postnatal age are influenced primarily by energy intake and weight gain. Energy expenditure increases with increases in metabolizable energy intake, indicating increased substrate oxidation or tissue synthesis. Van Aerde[111] observed that about one fourth of each additional kilocalorie absorbed is expended. If the preterm infant is growing at the same rate as the fetus during the third trimester—that is, gaining approximately 15 g/kg per day—then about 15% of the total energy intake is used for synthesis of new tissue.

Energy storage is a linear function of metabolizable intake and the accretion rate for energy is related more to the level of metabolizable energy intake than to diet composition. Energy requirements for energy storage are difficult to predict. The increase in tissue mass during growth includes the energy stored as protein, carbohydrate (usually less than 1% of body weight), and fat. Therefore, the energy stored can be assumed to equal the sum of the cost of protein plus fat gain. The energy storage component of the energy balance equation is a function of the composition of weight gain, which in turn is a function of protein and energy intake and is likely to be quite variable. Therefore the energy intake required to produce a specific rate of weight gain cannot be predicted without specifying the composition of that weight gain. From the point of view of energy storage, protein is a poor material, because a small quantity of energy is stored per gram of weight gain. Approximately the same amount of energy is deposited in 1 g of fat tissue as in about 8 g of lean tissue.

Most studies of enterally fed preterm infants receiving either human milk or formula report a higher rate of energy storage per gram of weight gain than that estimated for the fetus.[84] This may reflect an adaptation to extrauterine life, and if so, it may also be inappropriate to simulate rates of intrauterine energy and fat accretion. However, the effect of a large amount of weight gained as fat and the optimal rate of weight gain for these infants are presently unknown.[84]

Caloric requirements for healthy neonates are based on measurements of minimal metabolic rates and on theoretical estimates of caloric needs for normal physiologic functions. Total daily energy requirements for full-term infants increase sharply from fetal levels during the first 48 hours of life and continue to increase at a lower rate until the end of the second week of life, reaching a value of 100 to 120 kcal/kg per day. Unlike that for full-term infants, the optimal caloric requirement for infants with very low or extremely low birthweights is more difficult to define and is still to be determined for those infants and for critically ill neonates. For example, a recent study demonstrated that sepsis in extremely premature infants significantly increases energy expenditure to approximately 95 kcal/kg per day, compared with approximately 65 kcal/kg per day in extremely premature infants without sepsis.[107]

Premature infants have limited total body energy stores, so providing adequate early energy resources is more crucial for preterm neonates than for full-term infants, even without considering their greater normalized rate of in utero growth. Lacking a better standard, nutritionists have adopted the concept that the in utero growth and accretion rate is ideal. Absolute weight gain increases progressively over the second half of gestation; however, the weight-normalized weight gain decreases during this period. Thus nutritional requirements for fetal growth, when estimated from the specific weight of the fetus, are actually much higher at 24 to 28 weeks' gestation than they are at term.[34] Furthermore, actual weight gain is an underestimate of nutritional requirements, because changes in body composition during this period are not considered. The total water content of the fetus decreases from 90% at 20 weeks to 75% at term, and the size and number of cells increase during this period. Higher weight-normalized nutrient intakes are necessary to produce growth in infants with ELBW compared with older, more mature infants. Prenatal growth rate and body composition also may influence postnatal nutritional requirements. Greater weight-specific growth rates of 10th percentile infants who are small for gestational age compared with those of 90th percentile infants who are large for gestational age suggest that infants who are small for gestational age may require more nutrient intake per kilogram of body weight than larger infants.

According to the energy balance equation, the energy requirement for maintenance of existing weight and body composition is equal to energy expenditure. Individual infants vary in their activity, in their ease of achieving basal energy expenditure at thermoneutrality, and in their efficiency of nutrient absorption. Enteral intakes of 120 or 130 kcal/kg per day have been recommended, allowing most infants with low birthweights to grow at 15 to 20 g/day, similar to growth rates achieved in utero.[1,68] Increasing the energy intake to 140 to 150 kcal/kg per day increases weight gain and triceps-subscapular skinfold thickness but has no effect on gain in length or head circumference or in nitrogen retention.[118] Most preterm infants achieve acceptable weight gain at these levels of energy intake. Infants who are small for gestational age or infants with diseases that increase energy requirements may need higher intakes to achieve the same growth rates. Newborn infants with growth retardation often require an increased caloric intake for growth because of both higher maintenance energy needs and higher energy costs of new tissue synthesis.

The American Academy of Pediatrics[1] and the Canadian Paediatric Society[19] have recommended an average energy intake of 105 to 130 kcal/kg per day. At present, no valid recommendations can be made with regard to the optimal energy requirements for infants with ELBW or critically ill infants, except that their energy requirements are likely to be higher than those for stable, growing infants with VLBW. A recent study measured total energy expenditure of approximately 90 kcal/kg per day in infants with ELBW near hospital discharge, compared with approximately 60 kcal/kg per day in normal term infants.[48] Based on limited available data, a target enteral energy intake of 130 to 140 kcal/g per day may be reasonable for infants with ELBW.[34]

ELECTROLYTES

From calculations based on measurements of renal function and from reported data, a sodium intake between 3 and 5 mmol/kg per day (equivalent to between 3 and 5 mEq/kg per day) is usually sufficient to allow growth in orally fed infants weighing less than 1500 g and of less than 34 weeks' gestation during the first 4 to 6 weeks of life. Sodium concentrations should generally be maintained in the 135 to 140 mEq/L range. The sodium content of human milk is low, and the plasma sodium concentration must be monitored. Supplementation of 2 to 4 mmol/kg per day as sodium chloride may be necessary. For infants who weigh less than 1000 g, sodium and other electrolytes should be measured frequently to determine their needs accurately during the first 2 weeks of life; sodium supplements of 1 to 8 mmol/kg per day are often required. Premature formulas and fortified human milk provide only 2 to 3 mmol/kg per day at full enteral intake. Between 34 and 40 weeks, the requirements fall to about 1.5 to 2.5 mmol/kg per day. There is some evidence that sodium supplementation may improve growth as well as positively influence developmental outcome.[3]

MINERALS

The peak of fetal accretion of minerals occurs primarily after 34 weeks' gestation, and mineralized bones develop poorly in preterm infants fed low mineral intakes. The advisable intakes range from 70 to 200 mg calcium/100 kcal, 50 to 117 mg phosphorus/100 kcal, and 6 to 12 mg magnesium/100 kcal (Table 35-5). These recommended intakes are 3 to 4.5 times higher for calcium, 5 to 6 times higher for phosphorus, and 1.5 to 3 times higher for magnesium than the

composition of human milk. Mineral concentrations have been increased in preterm formulas and human milk supplements designed for feeding premature infants in an attempt to meet requirements. Significant increases in calcium and phosphorus content may affect magnesium retention. Several studies have shown improvement of mineral retention or bone mineralization in preterm infants who receive higher calcium and phosphorus intakes compared with their unsupplemented peers.[62,68]

Consumption of unfortified human milk by infants with VLBW after hospital discharge results in bone mineral deficits that persist through 52 weeks postnatally, indicating the need for additional minerals after discharge. Supplemental bioavailable calcium and phosphorus salts may be required by breast-fed preterm infants until their weight reaches term weight (3 to 3.5 kg).[64]

Iron

Preterm infants are at increased risk for the development of iron deficiency anemia because they deplete their stores from birth in half the time of a term infant (at about 2 months of age). Infants with VLBW or sick infants who are medically managed with frequent blood sampling lose much of the iron present in the circulating hemoglobin, which is then unavailable for erythropoiesis. The American Academy of Pediatrics, the Canadian Paediatric Society, and ESPGHAN agree on a recommendation of 2 to 3 mg/kg per day of dietary elemental iron, begun no later than 2 months of age in preterm infants and continued throughout the first year of life.[1,19,42] Iron intakes of 2 mg/kg per day begun at 2 weeks of age were shown to safely augment ferritin stores in infants with low birthweights without risk of vitamin E deficiency hemolytic anemia. This is achieved with standard iron-containing preterm formulas at full enteral intake. Premature infants receiving human milk require iron supplementation with ferrous sulfate. Higher intakes of 3 and 4 mg/kg per day begun by 1 month of age and continued through age 12 months are suggested for infants who weigh less than 1500 and 1000 g at birth, respectively.[39]

OTHER TRACE ELEMENTS

Trace elements contribute less than 0.01% of total body weight. They function as constituents of metalloenzymes, cofactors for metal ion activated enzymes, or components of vitamins, hormones, and proteins. The fetus accumulates stores of trace elements primarily during the last trimester of pregnancy. Therefore the premature infant has low stores at birth and is at risk for trace mineral deficiencies when intakes are not adequate to support requirements for growth. Immature homeostatic control of trace element metabolism also increases the risk of deficiency. Trace minerals that have established physiologic importance in humans include zinc, copper, selenium, manganese, chromium, molybdenum, fluoride, and iodine. The recommended oral intakes for infants are listed in Table 35-5.[1] The trace minerals that are potentially toxic in pediatric patients are lead and aluminum.

VITAMINS

Vitamins are organic compounds that are essential for metabolic reactions but are not synthesized by the body. They are therefore needed in trace amounts from enteral or parenteral sources. Higher amounts of select vitamins are required by preterm infants, who may have greater needs for growth or because of immature metabolic or excretory function. (See reference 47 for a comprehensive review of vitamin metabolism and requirements in extremely premature infants.)

The recommended oral intakes of vitamins for infants are compared in Table 35-6. Vitamins are classified as water soluble or fat soluble, based on the biochemical structure and function of the compound. Water-soluble vitamins include the B complex vitamins and vitamin C. They serve as prosthetic groups for enzymes involved in amino acid metabolism, energy production, and nucleic acid synthesis. Needs are considered relative to dietary intake of calories and protein, as well as the rate of energy use. Water-soluble vitamins cannot be formed by precursors (with the exception of niacin from tryptophan) and do not accumulate in the body (with the exception of vitamin B_{12}). Therefore daily intake is required to prevent deficiency. Excretion occurs in the urine and bile. Most water-soluble vitamins cross the placenta by active transport; vitamin C crosses by facilitated diffusion. Levels of water-soluble vitamins generally are higher in fetal than in maternal blood and are relatively independent of concentrations in the circulation of a

nourished mother. Preterm infants and infants of undernourished mothers have lower blood levels of water-soluble vitamins at birth.[47]

Altered urinary losses due to renal immaturity during the first week of life predispose a preterm infant to vitamin deficiency or excess. The need for vitamin C may be greater in a preterm infant who experiences increased urinary losses and lacks *p*-hydroxyphenylpyruvic acid oxidase, an enzyme that catabolizes tyrosine and is stimulated by vitamin C. Transient neonatal tyrosinemia, however, has not been shown to be detrimental to infants. A limited riboflavin intake (less than 300 mg/100 kcal) may be necessary in the first 3 weeks of life in an infant whose birthweight is less than 750 g and who demonstrates decreased urinary excretion and increased serum levels of riboflavin.[46]

Fat-soluble vitamins include vitamins A, D, E, and K. These vitamins function physiologically on the conformation and function of complex molecules and membranes and are important for the development and function of highly specialized tissues. They can be built from precursors, are excreted with difficulty, and accumulate in the body, potentially producing toxicity. They are not required daily, and deficiency states develop slowly. Fat-soluble vitamins require carrier systems, usually lipoproteins, for solubility in blood, and intestinal absorption depends on fat absorption. They cross the placenta by simple or facilitated diffusion. Accumulation takes place throughout pregnancy and depends on maternal blood levels. Therefore, blood concentrations and body stores at birth are lower than normal in preterm infants and in infants of poorly nourished mothers.

The recommendation for vitamin A for preterm infants includes increased intakes for infants with lung disease.[92] These higher intakes are considered safe and may promote regenerative healing from lung injury, possibly reducing the incidence and severity of bronchopulmonary dysplasia.

The recommendations for vitamin D for preterm infants differ significantly throughout the world, with an upper limit as high as 1600 IU/day. Multiple studies have not demonstrated any advantage of high vitamin D intakes, and 400 IU/day appears to be adequate for preterm infants, particularly those with generous mineral intakes.[64]

Vitamin E in formula, required as 0.6 mg/g of polyunsaturated fatty acid, provides adequate amounts to prevent hemolysis of red blood cell membranes when iron intake is not excessive. The recommended total intake is 3 to 4 IU/day for term infants. Pharmacologic supplementation of vitamin E is not recommended in premature infants to reduce the incidence or severity of retinopathy of prematurity, bronchopulmonary dysplasia, or intraventricular hemorrhage.[1]

An adequate intake of vitamin K to prevent bleeding in the first week of life when enteral intakes are low is recommended as a 1-mg IM injection at birth in both term and preterm neonates weighing more than 1000 g at birth. For premature infants less than 1000 g birthweight, 0.3 mg is recommended.[1] Term infants can be given 2 mg orally as an alternative. Thereafter, 2 to 3 mg/kg per day or 5 to 10 mg daily is recommended in all infants.

PREBIOTICS AND PROBIOTICS

Several randomized clinical trials of probiotics have been performed in neonates and have suggested that administration of probiotics may prevent necrotizing enterocolitis.[12,33,55] However, further studies are required to establish safety and efficacy of probiotics for the prevention of necrotizing enterocolitis.

HUMAN MILK AND FORMULA

Human milk is the optimal food for term infants because it provides immunologic and antibacterial factors, hormones, enzymes, and opioid peptides not present in alternative infant food sources. The benefits of human milk for gastrointestinal function, host defense, and possibly neurodevelopmental outcome have been well documented.[1]

There is general consensus that human milk is also the optimal primary nutritional source for premature infants. The strongest evidence of the benefit of human milk for premature infants is the reduced incidence of necrotizing enterocolitis.[89] Other benefits include improved gastric emptying, reduced infections, and possibly better neurocognitive development.[7]

The milk from mothers of preterm infants contains more protein and electrolytes than does milk from mothers of term infants. However, these concentrations decline and approach the composition of term human milk in several weeks. Human milk does not completely meet the nutritional needs of premature infants; insufficient protein, calcium, phosphorus, sodium, zinc, vitamins, and possibly energy are provided by human milk to optimally support most premature infants. Human milk fortifiers address many of these inadequacies (Table 35-7).

Premature infants fed fortified human milk may have growth rates slightly lower than those of infants fed formula, but they may also achieve earlier discharge.[89] Human milk fortifiers should be used in premature infants with birthweights less than 1500 g and should be considered in those with birthweights less than 2000 g.

PRETERM FORMULAS

Formulas for premature infants have been developed to meet the nutritional needs of growing preterm infants and have been used for more than 20 years. The design and testing of these formulas did not specifically include extremely premature (less than 1000 g) infants. Premature formulas contain a reduced amount of lactose (40% to 50%) because intestinal lactase activity may be low in premature infants. The remainder of the carbohydrate content is in the form of glucose polymers, which maintain low osmolality of the formula (300 mOsm or less with a caloric density of 80 kcal/dL). The fat blends of preterm formulas are 20% to 50% MCTs to compensate for low intestinal lipase and bile salts. It is not clear that MCTs are necessary in premature infant formulas.[19,62] The protein content of preterm formulas is higher than that of term formulas (2.7 to 3 g/100 kcal), which promotes a rate of weight gain and body composition similar to that of the reference fetus. Premature formulas are whey predominant, which reduces the risk of lactobezoar formation and may provide a more optimal amino acid intake. Calcium and phosphorus content is also higher in preterm formulas, which results in improved mineral retention and bone mineral content. The vitamin levels of premature formulas vary, and some may require vitamin supplementation. The composition of a number of premature formulas is listed in Table 35-8.

SPECIALIZED FORMULAS

Occasionally, infants do not tolerate feedings and require formulas specifically designed for conditions of malabsorption or other types of formula intolerance. These formulas are free of lactose and cow's milk protein and provide alternative sources of protein (soy, casein hydrolysates, free amino acids) and carbohydrate (sucrose, corn syrup solids, tapioca starch, cornstarch). Some provide a significant percentage of the fat as MCTs. Specialized formulas are somewhat higher in protein and mineral content but similar in vitamin composition compared with formulas designed for term babies. The vitamin and mineral contents are therefore lower compared with formulas and human milk supplements designed for preterm infants. Multivitamin and mineral supplementation of specialized formulas is generally necessary to provide the recommended intakes for premature infants. Specialized formulas have not been tested in premature infants and therefore are used only temporarily, when necessary. Routine feedings for preterm infants are reinstituted as tolerated.

PRETERM DISCHARGE FORMULAS

It was common practice in the past to feed premature infants premature formula until discharge and then switch to term formula. However, most premature infants are discharged at far less than term weight and may have ongoing and catch-up requirements that may not be met by term formulas. Three large randomized, controlled trials have compared standard infant formula with a preterm infant discharge formula.[22,70,71] Preterm infant discharge formulas have a nutrient content between preterm and standard term formulas. Improvements in weight and length have been measured in preterm infants receiving the discharge formulas. One study also demonstrated increases in head circumference in preterm infants with birthweights less than1250 g, who received the discharge formulas.[22] The use of preterm discharge formulas should be strongly considered for premature infants with birthweights less than 1500 g for a period of 9 to 12 months. Premature infants with chronic lung disease may also benefit from enriched nutrient intakes, especially additional protein, calcium, phosphorus, and zinc.[16] The composition of a number of premature discharge formulas are listed in Table 35-8.

SUPPLEMENTATION OF INFANT FEEDINGS

Term Infants

Supplementation for healthy term breast-fed infants is usually not necessary, except for vitamin D. To prevent rickets, the American Academy of Pediatrics recommends that breastfed infants receive 400 IU per day of vitamin D beginning soon after birth.[116]

Breast-fed infants usually require an additional iron source after 4 to 6 months of age.[1] Standard infant formulas that are iron fortified (1.8 mg iron/100 kcal) provide adequate iron for term infants. Current recommendations are for fluoride supplementation only after 6 months of age.[1]

No vitamin supplements are necessary for term formula-fed infants who consume at least 1000 mL of infant formula daily. Term infants with chronic diseases that result in intake of formula or human milk less than 1000 mL per day may require additional supplementation of vitamins and minerals to meet recommended daily allowances.

Infants who experience abnormal gastrointestinal losses (persistent diarrhea or excessive ileostomy drainage) often require supplementation with zinc and electrolytes.

Preterm Infants

Daily multivitamin or mineral preparations may be necessary for preterm infants once enteral feedings have been established. Preterm formulas and human milk fortifiers differ in the amounts of vitamins and minerals they contain; therefore the need for supplementation varies for infants with VLBW.

Preterm infants who require specialized formulas or receive standard infant formulas require supplementation with vitamins and minerals to provide the recommended intakes. Multivitamin supplements that contain the equivalent of the recommended daily allowances for term infants can be given (see Table 35-6). Liquid multivitamin drops do not contain folic acid because of its lack of stability, but it can be added or given separately.

Breast-fed infants who weigh less than 3.5 kg do not consume enough human milk to acquire the recommended intakes of some vitamins and minerals. Therefore supplementation with a multivitamin, folic acid, calcium, phosphorus, zinc, and

iron may be necessary, unless one of the commercially available milk fortifiers is used.

INITIATION AND ADVANCEMENT OF ENTERAL FEEDING

The diversity of approaches to feeding preterm infants underlines the need for studies to dispel myths and find reasonable solutions to the problem of what feeding route to use, which has plagued pediatricians and neonatologists for years. Once suitable TPN solutions for neonates were available, many physicians chose to use strictly parenteral nutrition in sick preterm infants because of concerns about necrotizing enterocolitis. TPN was thought to be a logical continuation of the transplacental nutrition the infants would have received in utero. However, this view discounts any role that swallowed amniotic fluid may play in nutrition and in the development of the gastrointestinal tract. In fact, by the end of the third trimester, amniotic fluid provides the fetus with the same enteral volume intake and approximately 25% of the enteral protein intake of a term breast-fed infant.[69]

Over the past 10 years, investigators have been looking at the utility of minimal enteral feedings. Minimal enteral feedings involve hypocaloric, low-volume enteral nutrition that does not contain sufficient calories to sustain somatic growth. Proposed benefits include maturation of the preterm intestine (both structurally and functionally), reduced liver dysfunction, and improved feeding tolerance. There is direct and indirect evidence of a benefit from minimal enteral feedings without an increase in the incidence of necrotizing enterocolitis.

Animal studies have been done to evaluate some of the anatomic, histologic, and enzymatic differences between enteral and parenteral feeding. Levine and coworkers compared rats receiving intravenous TPN with those receiving the same solution enterally. After 1 week they found gut weight decreased by 22%, mucosal weight by 28%, mucosal protein by 35%, DNA by 25%, in fasted rats (i.e., those who received TPN instead of enteral feeds).[3,67] Other investigators confirmed these findings.[23] Thus it appears that enteral feedings may be necessary to maintain the integrity and enhance the maturation of the gastrointestinal tract.

Studies of preterm infants have evaluated gut hormone levels and the maturation of gastrointestinal motility in response to minimal enteral nutrition. Lucas evaluated enteroglucagon, gastrin, gastric inhibitory peptide, motilin, and neurotensin in premature infants; these hormones are thought to be important in producing changes in function or growth of the gastrointestinal tract.[69] In response to small volumes of enteral feedings in these premature infants, significant elevations of all these hormones were demonstrated. Berseth and associates used low-compliance perfusion manometry to evaluate the maturation of motility and found that infants who received nutrient feedings (as opposed to sterile water) displayed significant changes in intestinal motor activity in response to feeding.[11] Furthermore, these infants achieved full enteral feedings and full nipple feedings earlier than did their counterparts who were fed sterile water.[11] Shulman and coworkers demonstrated that premature infants who received early feeding had decreased intestinal permeability and increased lactase activity at 10 days of age compared with late-fed controls.[94,95]

Supported by these animal and physiologic studies, multiple clinical trials evaluating minimal enteral feeding have been performed.[74,108] Although many of these trials were relatively small (60 patients or fewer), the more recent studies included 100 patients or more. Although study protocols varied significantly, mean birthweight was generally 1000 g and gestational age 28 weeks, and most subjects required mechanical ventilation. Early feedings were begun about 3 days of age and consisted of human milk or formula at 12 to 24 mL/kg per day. The results of these studies were heterogeneous, but three or more studies measured a reduction in hospital stay, days to full feedings, and feeding intolerance in the early feeding group. Other benefits observed included improved gastrointestinal motility, increased calcium and phosphorus absorption, and reduced sepsis and sepsis evaluations. Adverse effects of early feeding were not observed in any of the studies, and the incidence of necrotizing enterocolitis, in particular, was not different between early- and late-fed premature infants. A Cochrane Review, which has not included the more recent large trials, reported early minimal feeding produced significant reductions in number of days to full enteral feeding, total days that feedings are withheld, and days of hospital stay.[108]

In summary, the data from these studies support physiologic and clinical benefit from early minimal enteral feeding, without an increased risk of necrotizing enterocolitis. Although a large multicenter trial that more clearly evaluates early feeding may be desirable, such a trial appears unlikely. The available evidence strongly supports initiating early enteral feeding.[63]

The optimal rate of feeding delivery in tube-fed infants has also been a matter of controversy and may reflect regional differences as well as differences in interpretation of the scientific data. Infants appear to tolerate feedings better if rapid gastric distention is avoided. However, continuous drip feedings that deliver milk very slowly have their own potential hazards. Continuous drip feedings may be even more hazardous to infants receiving breast milk, because colonization of expressed milk is universal, and logarithmic growth of bacteria occurs in milk left at room temperature for more than 6 hours. Another disadvantage of continuous drip breast milk feedings is the potential loss of nutrient delivery (up to 34% of the expressed milk fat). Moreover, a recent large randomized study demonstrated increased feeding intolerance and decreased growth in premature infants fed continuously compared with those fed by bolus.[90] Although some premature infants may require continuous feedings, bolus feedings over 20 to 25 minutes are generally recommended as a first approach. Bolus feedings are usually delivered in equal volumes every 3 to 4 hours for term infants, every 3 hours for infants weighing less than 2500 g, and every 2 to 3 hours for infants weighing less than 1500 g. Gastric emptying may be a clinical problem but is enhanced with human milk feedings and when infants are in the prone or right-sided position. Gastric emptying is prolonged by increasing feeding density.

The substrate used to initiate feedings and the rate of advancement are controversial topics without a great deal of data. There is general consensus that given the advantages of breast milk (including tolerance), it should be the first choice and can be used undiluted. Diluting premature formulas for initial feedings is common clinical practice, but there is little data to support this approach. There is some evidence that undiluted formula may better promote duodenal motor responses in preterm infants.[8] The rate at which enteral feedings should be advanced in infants with VLBW is also unclear from available data. A number of retrospective studies suggested that rapid advancement of feedings (greater than 25 mL/kg per day) may increase the risk of necrotizing enterocolitis.[5,75] Two randomized trials compared advancing feedings at 15 to 20 mL/kg per day and 30 to 35 mL/kg per day; no difference in necrotizing enterocolitis was observed between the two groups in either study.[5,75] A single center randomized controlled trial compared two approaches in premature infants: prolonged small enteral feedings (20 mL/g per day for 10 days) and advancing feedings by 20 mL/g perday.[11] A reduced incidence of necrotizing enterocolitis was measured in the group receiving prolonged small feedings. Although this study may not be entirely definitive, a period of prolonged small feedings for preterm infants deserves some consideration.

PRACTICAL APPROACH TO ADMINISTRATION OF PARENTERAL AND ENTERAL NUTRITION

The following are practical guidelines for administering parenteral and enteral nutrition to premature infants. These recommendations are intended to present a reasonable approach to parenteral nutrition based on the available data.

Intravenous amino acids should be started as early as possible, preferably on the first day of life. A pediatric crystalline amino acid mixture should be used and based on currently available data; a minimum of 3 g/kg per day of amino acids should be provided. Many institutions have a “neonatal stock amino acid solution.” This solution, made in advance by the pharmacy, is comprised of a neonatal amino acid solution mixed in 7.5% dextrose. When infused at a standardized rate of 60 mL/kg per day, the solution provides 3 g/kg per day of amino acids. TPN can be started the following day or two, depending on the fluid and electrolyte status of the infant. No data support the need to advance amino acid intake slowly as has been the routine practice in the past in many nurseries.

Glucose should be provided in the parenteral nutrition solution to maintain normal plasma glucose concentrations and to meet the demand for glucose use. As discussed earlier in this chapter, the glucose production and utilization rates in a term infant are approximately 3 to 4 mg/kg per minute, whereas a premature infant has a much greater need, 6 to 8 mg/kg per minute. Infants who weigh 1000 g or more usually tolerate a 10% glucose solution initially, whereas infants weighing less than 1000 g probably need to be started on a 5% glucose solution, given their higher total fluid requirements and predisposition toward hyperglycemia.

Lipids can be started as early as the first day of life. Starting concentrations of 0.5 to 1 g/kg per day, infused over 24 hours using a 20% emulsion, should be well tolerated, even by infants with VLBW. Lipid concentrations can gradually be advanced to a maximum of 3 g/kg per day while normal serum triglyceride levels are monitored and maintained.

The appropriate balance of glucose and lipid in parenteral nutrition is critical for achieving maximal nutritional benefit. In fact, nutrient and protein retention is maximal if the nonprotein caloric balance between carbohydrate and lipid is approximately 60:40. This more closely mimics the fat content of breast milk and minimizes excess energy expenditure, which can occur if a disproportionate amount of nonprotein calories is given as glucose. Even at higher protein intakes, a parenterally fed infant with ELBW may need 80 to 90 kcal/kg per day for nonprotein energy supplies. The caloric requirements of a parenterally fed neonate are much lower than those fed enterally. It is important to realize that providing excessive calories via parenteral nutrition does not correlate with higher rates of growth. In addition, it should be emphasized that it is not difficult to provide adequate nonprotein energy, and it can be done without using highly concentrated glucose solutions. This considered, glucose concentrations above 12.5% should be required only on rare occasions. In addition, glucose concentrations above 10% to 12.5% should be reserved for use with central venous access.

Electrolytes, minerals, and vitamins also should be included in the standard parenteral nutrition solution. Parenteral nutrition, once initiated, probably should be continued until enteral feedings supply approximately 100 to 110 kcal/kg per day. Understanding the optimal means of providing nutrition to neonates is an ongoing process. As survival of premature infants continues to improve, research efforts must focus on maximizing nutritional support.

The following general guidelines represent one approach to enteral feeding of the infant with ELBW. As intravenous parenteral nutrition is being provided and advanced, minimal early enteral intake for the infant with ELBW should be strongly considered, beginning at day 2 or 3 of life. The requirement for mechanical ventilation or the presence of an umbilical arterial line should not prevent initiating minimal enteral feeding. Breast milk from the infant’s mother is the preferred enteral substrate; it is usually provided undiluted and ultimately fortified with a standard breast milk fortifier when the infant has achieved full-volume feeds. If breast milk is unavailable, undiluted premature formulas can be provided; there is little support for the use of diluted formulas. Small aliquots of human milk or premature formula may be provided by the orogastric route on a regular intermittent schedule (1 to 2 mL/kg every 2 to 3 hours). Evidence suggests that such minimal intake is well tolerated and may reduce or prevent intestinal atrophy in this high-risk population.[74] Early minimal enteral intake is not intended to provide significant nutrition to the infant; rather, it is thought to serve as a priming nutrient source for the intestine, sustaining continued functional maturation postnatally.

The appropriate pathway to achieving full enteral feedings in premature newborns is an area that often generates strong opinions based on limited or incomplete data. One common approach is to advance feedings by 20 mL/kg per day if the infant tolerated the previous 24 hours of feeding; this typically results in full enteral feeding (150 mL/kg per day) in 7 to 10 days. This slow rate of advancement is based on several retrospective studies that examined the risk factors associated with necrotizing enterocolitis.[5,75] More recent data suggest that prolonging small feeding volumes for a period of time may reduce necrotizing enterocolitis.[11] Some period (5 to 10 days) of small enteral feedings (20 mL/kg per day) should be considered before advancing, especially in the high-risk ELBW infant population. Throughout the process of advancing feeds, adjustments are made if signs and symptoms of feeding intolerance are observed (e.g., residuals, abdominal distention, blood in stools, increased respiratory distress). However, because most of these signs and symptoms are nonspecific, it often is less than clear what the optimal clinical response should be.

A number of other considerations are important for infants with ELBW as enteral feeds approach full volumes, usually 150 to 160 mL/g per day. Existing preterm formulas were not designed for this population, and there is evidence that current formulas do not provide adequate nutrients for catch-up growth or produce acceptable growth outcomes.[41,66] Strong consideration should be given to using an increased caloric density preterm formula (27 kcal/oz) by adding both protein and nonprotein calories. Increasing the caloric and protein density can be accomplished in a variety of ways, but none of these have been tested in clinical trials.

CHAPTER 36

Fluid, Electrolytes, and Acid-Base Homeostasis

Fluid and electrolyte and acid-base management are essential components in the care of neonates who are considered high risk. This is particularly true for infants with very low birthweight for several reasons. Premature neonates typically require parenteral fluids, the quantity and composition of which can be highly variable. They also have important developmental limitations in renal homeostatic mechanisms. Finally, immature infants may be particularly susceptible to significant morbidity and mortality related to fluid and electrolyte and acid-base imbalances.

PART 1

Fluid and Electrolyte Management

Katherine MacRae Dell

In this section, basic renal mechanisms for maintaining fluid and electrolyte homeostasis are reviewed, and factors that govern fluid and electrolyte requirements for term and preterm infants are outlined. Methods for monitoring fluid and electrolyte balance, and potential complications and treatments of fluid and electrolyte disorders are discussed. Also, several specific situations in high-risk infants that require special consideration are addressed.

BODY FLUID COMPOSITION IN FETUSES AND NEWBORNS

Total body water (TBW) encompasses extracellular (interstitial and plasma) and intracellular water. Early in fetal development, TBW is almost 95% of the total body weight. As the fetus grows, there is a decrease in the proportion of body weight represented by water (Fig. 36-1).[12] By birth, TBW represents approximately 75% of body weight in a full-term infant. The progressive decrease in TBW is due primarily to decreases in the extracellular water compartment. Premature, particularly very premature, infants have a higher TBW content than term infants, and that increase is primarily extracellular water.

During the first week of life, all healthy neonates experience a reduction in body weight. The major cause of this physiologic weight loss is a reduction in extracellular water.[42] In the first 24 to 48 hours after birth, infants have decreased urine output, followed by a diuresis phase, with urinary losses of water and sodium in the first week of life resulting in weight loss.[27] In term infants, this physiologic weight loss typically can be 10%. In very premature infants, the loss of extracellular fluid (ECF) can be 15%, however.[44] The physiologic weight loss in the first few days of life in term and premature infants represents isotonic contraction of body fluids, and seems to be part of a normal transitional physiologic process, although the precise mechanisms underlying this process are unclear. Perturbations in this normal transitional physiology can lead to imbalances in sodium and water homeostasis. In ill term infants and premature infants, various factors (discussed subsequently) can lead to increased or decreased urinary or insensible water losses. Similarly, increased or decreased administration of intravenous fluids, with variable amounts of water and sodium, can have a significant impact on overall fluid balance.

SODIUM BALANCE IN NEWBORNS

Sodium is the major component of the ECF volume and plasma volume. The total sodium content (*not* the serum sodium concentration) determines the volume of the ECF. Renal sodium handling is crucial in maintaining sodium balance and protecting against volume depletion or overload. Sodium is freely filtered by the glomerulus, and the bulk of the filtered sodium is reabsorbed in the proximal tubule. Additional sodium reabsorption occurs in the loop of Henle via the Na^+-K^+-2 Cl^- cotransporter, the therapeutic target of loop diuretics. In the distal convoluted tubule, sodium is further reabsorbed via the sodium chloride cotransporter, the therapeutic target of thiazide diuretics. The major site of fine regulation of sodium reabsorption is the collecting tubule, where aldosterone acts on the principal cells to promote

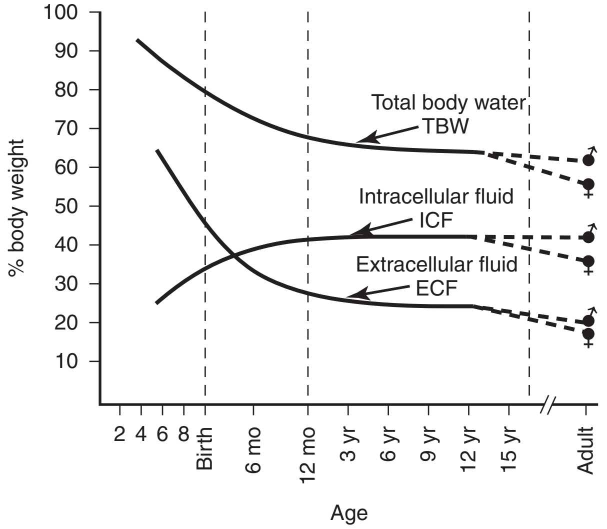

Figure 36–1. Change with age in total body water and its major subdivisions. *(From Friis-Hansen B: Body water compartments in children: changes during growth and related changes in body composition,* Pediatrics *28:169, 1961. Used with permission of American Academy of Pediatrics.)*

reabsorption through sodium channels located on the luminal membrane.

Healthy term neonates have basal sodium handling similar to that of adults, with a fractional excretion of sodium (FE_{NA}) of less than 1%, although a transient increase in FE_{NA} occurs during the diuretic phase on the second and third days of life.[27] In premature infants, however, renal sodium losses are inversely proportional to gestational age, with FE_{NA} equalling 5% to 6% in infants born at 28 weeks' gestation (Fig. 36-2).[45] As a result, preterm infants may display negative sodium balance and hyponatremia during the initial 2 to 3 weeks of life because of high renal sodium losses and inefficient intestinal sodium absorption.[48] The mechanisms responsible for increased urinary sodium losses in preterm infants are multifactorial. The immature kidney exhibits glomerulotubular imbalance, a physiologic state that is present when the glomerular filtration rate (GFR) exceeds the reabsorptive capacity of the renal tubules. This imbalance is due to numerous factors, including a preponderance of glomeruli compared with tubular structures, renal tubular immaturity, large extracellular volume, and reduced oxygen availability.[35] Decreased responsiveness to aldosterone is also characteristic of fetal and postnatal kidneys compared with adult kidneys, and results in a decrease in sodium reabsorption.

Urinary sodium losses in preterm and term neonates may be increased in certain conditions, including hypoxia, respiratory distress, hyperbilirubinemia, acute tubular necrosis, polycythemia, increased fluid and sodium intake, and theophylline or diuretic administration. Pharmacologic agents, such as dopamine, beta blockers, and angiotensin-converting enzyme inhibitors, which affect adrenergic pathways in the kidney and the renin-angiotensin axis, may also increase urinary sodium losses in neonates.

The abnormalities in sodium and water balance seen in premature infants are attenuated, to some degree, by prenatal steroid administration. Prenatal steroid treatment is associated with decreased insensible water loss, a decreased incidence of hypernatremia, and an earlier diuresis and natriuresis.[30] This beneficial effect on water and sodium balance in infants with extremely low birthweight is thought to be mediated by maturation of the renal epithelial transport systems controlling fluid and electrolyte homeostasis.

WATER BALANCE IN NEWBORNS

Water balance is controlled primarily by antidiuretic hormone (ADH), which controls water absorption in the collecting duct. ADH secretion is regulated by hypothalamic osmoreceptors that monitor serum osmolarity and baroreceptors of the carotid sinus and left atrium that monitor intravascular blood volume. Stimulation of ADH secretion occurs when serum osmolarity increases to greater than 285 mOsm/kg, or when effective blood volume is significantly diminished. Increases in serum osmolarity also stimulate thirst receptors in the anterior hypothalamus to promote increased water intake. Intravascular volume has a greater influence on ADH secretion than serum osmolarity. Patients with hyponatremia and concomitant volume depletion are unable to suppress ADH in response to the decrease in serum osmolarity.

At baseline, when the serum osmolarity and effective blood volume status are normal, the collecting duct is impermeable to water. In response to an increase in serum osmolarity or significant volume contraction, ADH produced in the hypothalamus binds to its receptor, arginine-vasopressin V2 receptor, located on the basolateral membrane of principal and inner medullary collecting duct cells. Receptor activation results in elevated levels of intracellular cyclic adenosine monophosphate. Downstream signaling pathways promote movement of preformed vesicles containing aquaporin 2 (AQ2) water channels to the apical surface. The presence of these water channels on the watertight apical membranes renders them permeable to water. Withdrawal of ADH stimulates endocytosis of AQ2-containing vesicles, which restores the collecting duct cells to a state of water impermeability.

This system may not be as straightforward as previously believed, however, because vasopressin V2 receptors have been shown to be expressed in nephron segments other than the collecting duct, notably the loop of Henle.[29] This study and others support the emerging concept of crosstalk between the ADH/vasopressin V2 receptor system (classically considered a regulator of water homeostasis only) and the renin-angiotensin system (classically considered a sodium regulator only), which may modulate renal handling of salt and water further.

Maximal renal concentration and dilution require structural maturity, well-developed tubular transport mechanisms, and an intact hypothalamic–renal vasopressin axis. In adults and older children, decreased water intake or increased water losses activate a highly efficient renal concentrating mechanism that can produce a maximally concentrated urine with an osmolarity of 1500 mOsm/kg, resulting in fluid conservation. Conversely, excessive fluid intake triggers the diluting mechanism of the kidney that can produce a maximally dilute urine with an osmolarity of 50 mOsm/kg, resulting in free water excretion.

Neonatal kidneys, particularly the kidneys of premature infants, are less able to concentrate urine efficiently.[8,28] When challenged, term newborns can concentrate urine to an osmolarity of 800 mOsm/kg; preterm infants can concentrate urine to an osmolarity of only 600 mOsm/kg.[8] This diminished urinary concentrating ability, particularly in preterm infants, may limit a neonate's ability to adjust to fluid perturbations—notably perturbations that result in increased free water losses (e.g., increased insensible water losses). Multiple factors limit renal concentrating capacity in preterm infants. Structural immaturity of the renal medulla limits sodium, chloride, and urea movement to the interstitium. Preferential blood flow through the vasa recta limits generation of a medullary gradient. Diminished urea-generated osmotic gradient in the renal medulla limits production and maintenance of the countercurrent mechanisms that are essential in producing a maximally concentrated urine. Finally, tubular responsiveness to vasopressin is diminished because of decreased transcription and protein synthesis of AQ2 water channels.[50]

Discrepancies are also seen in the diluting capabilities of term versus preterm infants. When challenged with a water load, term infants can produce a dilute urine with an osmolarity of 50 mOsm/kg, similar to that of an older child or adult. In contrast, the kidneys of preterm infants may be capable of diluting the urine to an osmolarity of only 70 mOsm/kg.[28,39]

The diminished urinary diluting and concentrating capacities of neonates have important implications for their care. Excessive fluid restriction places newborns, particularly preterm neonates, at risk for dehydration or hypernatremia or both. Conversely, generous fluid intake poses the risk of intravascular volume overload or hyponatremia or both. High fluid intake has also been associated with an increased risk of symptomatic patent ductus arteriosus (PDA) and necrotizing enterocolitis.[5,6] These facts underscore the importance of careful calculation of fluid and electrolyte requirements and close monitoring of fluid balance in high-risk neonates.

CALCULATION OF FLUID AND ELECTROLYTE REQUIREMENTS

Calculation of fluid and electrolyte requirements in newborns is based on maintenance needs, deficits, and ongoing losses. Crucial factors that determine these fluid requirements include gestational age, renal function, ambient air temperature and humidity, ventilator dependence, presence of drainage tubes, and gastrointestinal losses.[7]

Maintenance Fluids and Electrolytes

Maintenance fluid requirements represent the water required to maintain a newborn in neutral water balance. The total amount of maintenance fluid required is equal to urine production plus insensible losses. Table 36-1 summarizes maintenance fluid requirements during the first month of life for full-term and preterm infants. The numbers presented in Table 36-1 are only guidelines; they are to be used as a starting point for prescribing maintenance fluid for infants with low birthweight during the first week of life. Further adjustments must be based on the clinical situation. In particular, close attention to the patient's volume status and assessment of factors that may increase or decrease the baseline fluid requirements are essential to the appropriate management of these infants.

Insensible Losses

Insensible water losses are primarily evaporative losses via the skin and respiratory tract. In newborns, one third of insensible water loss occurs through the respiratory tract, and the remaining two thirds occurs through the skin. Numerous physiologic, environmental, and therapeutic factors can influence insensible water loss, making it the most variable component of the maintenance fluid requirements in newborns. Table 36-2 summarizes the effect of various factors on the degree of insensible water loss in newborns. Transepidermal water loss contributes significantly to increased insensible losses of premature infants (Fig. 36-3).[13] There is an inverse relationship between body weight and insensible water loss in a neutral thermal environment with moderately high relative humidity.[49] Factors that contribute to these increased losses in preterm versus term infants include greater water permeability through a relatively immature epithelial layer of skin, a higher surface area-to-body weight ratio, and increased skin vascularity. Although prenatal glucocorticoids promote

TABLE 36–1 Maintenance Fluid (Water) Requirements during the First Month of Life

		TOTAL WATER REQUIREMENTS BY AGE (mL/kg/d)		
Birthweight (g)	**Insensible Water Loss (mL/kg/d)**	*Day 1-2*	*Day 3-7*	*Day 8-30*
<750	100+	100-200	120-200	120-180
750-1000	60-70	80-150	100-150	120-180
1001-1500	30-65	60-100	80-150	120-180
>1500	15-30	60-80	100-150	120-180

Adapted from Veille JC: AGA infants in a thermoneutral environment during the first week of life, *Clin Perinatol* 15:863, 1988; Taeusch W, Ballard RA, editors: *Schaffer and Avery's diseases of the newborn,* 6th ed, Philadelphia, 1991, Saunders; Lorenz J et al: Phases of fluid and electrolyte homeostasis in the extremely low birth weight infant, *Pediatrics* 96:484, 1995.

TABLE 36–2 Factors Affecting Insensible Water Loss in Newborns

Factor	Effect on Insensible Water Loss
Level of maturity	Inversely proportional to birthweight and gestational age (see Fig. 36-3)
Environmental temperature above neutral thermal zone	Increased in proportion to increment in temperature
Elevated body temperature	Increased by up to 300% at rectal temperature >37.2°C
High ambient or inspired humidity	Reduced by 30% if ambient or respiratory vapor pressure equals skin or respiratory tract vapor pressure
Skin breakdown (e.g., burn)	Increased; magnitude depends on extent of lesion
Congenital skin defects (e.g., large omphalocele)	Increased; magnitude depends on size of defects
Radiant warmer	Increased by about 50% above values obtained in incubator setting with moderate relative humidity and neutral thermal environment
Phototherapy	Increased by up to 25%, depending on technique
Double-walled incubator or plastic heat shield	Reduced by 10%-30%

maturation of the renal tubules, they do not have a similar effect on skin maturation.[16] Infants who have conditions associated with skin breakdown, such as burns or large skin defects such as omphaloceles, also have increased transepidermal water loss. Phototherapy may increase insensible water losses by up to 25% dependent on technique employed.

Ambient temperature and relative humidity play an important role in influencing transepidermal water loss.[3,4,13] An increase in ambient temperature results in increased insensible water loss. A decrease in ambient temperature has no effect on insensible water loss, however, despite the fact that it increases energy expenditure on the basis of cold stress. When ambient temperature is held constant, a lower ambient humidity increases skin water losses because of increased vapor pressure on the skin surface compared with the ambient vapor pressure; this is particularly true for very premature infants. A decrease in humidity from 60% to 20% results in an increased water loss of 100% in infants of less than 26 weeks' gestation.[1] Alternatively, in the presence of high relative humidity, water evaporation is less. Similarly, infants on mechanical ventilation, which provides a humidified oxygen delivery system, also have reduced water evaporation from the respiratory tract.

Urinary Losses

The quantity of water required for the formation of urine depends on two major factors: the degree of renal function and the renal solute load. Under normal conditions, a major determinant of renal water requirement is renal solute load. Renal solute load is derived from exogenous and endogenous sources. During the first 1 to 2 days of life, the exogenous solute load of infants with low birthweight may be low. Because they are not usually fed enterally, caloric delivery by intravenous glucose-containing solutions does not meet basal energy needs. In the first 1 to 2 days of life, the basal energy requirement for infants with low birthweight is approximately 50 kcal/kg body weight. Currently, many infants are started on intravenous hyperalimentation on day 1 to 2. If they are started at 70 to 90 mL/kg per day of a 10% glucose solution, the caloric intake is 35 kcal/kg per day. These infants must derive the remaining mandatory energy requirement from an endogenous source (i.e., catabolism). This

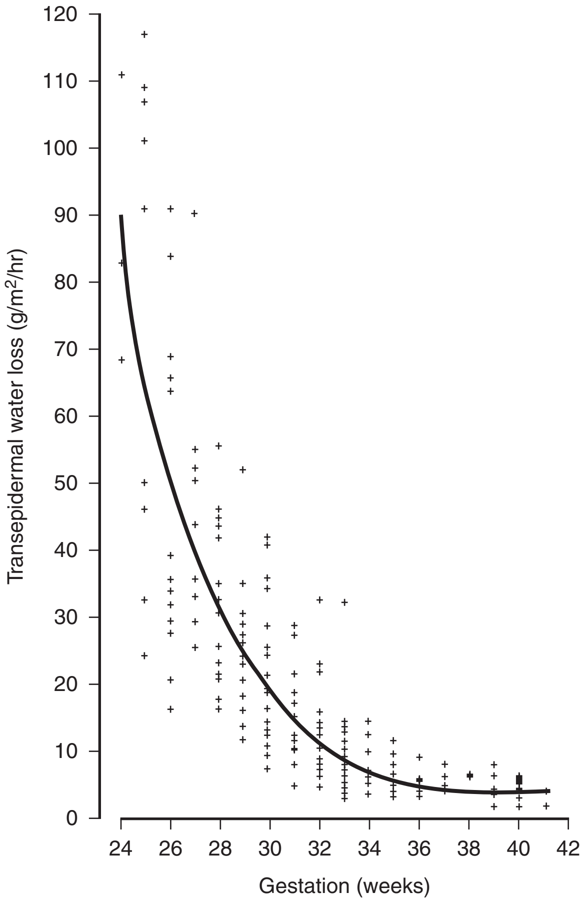

Figure 36–3. Effects of gestation on transepidermal water loss. Measurements were made from abdominal skin and carried out in the first few days of life. *(From Hammarlund K et al: Transepidermal water loss in newborn infants, III: relation to gestational age,* Acta Paediatr Scand *68:795, 1979.)*

catabolic state produces approximately 6 mOsm/kg per day of an endogenous solute load presented to the kidney. Assuming the infant can produce a maximal urinary concentration of 600 mOsm/kg, a minimum of 10 mL/kg per day of free water is required to excrete this solute load.

As the infant ages, the exogenous intake from parenteral or enteral sources increases, resulting in increased caloric intake. The result is that the exogenous solute load increases, whereas catabolism decreases, resulting in a decreased endogenous solute load. It estimated that by 2 or 3 weeks of age, an infant consuming 80 to 120 kcal/kg per day has a total solute load of approximately 15 to 20 mOsm/kg per day. Assuming that the infant can produce a maximal urinary concentration of 800 mOsm/kg by this age, 20 to 25 mL/kg per day of free water is required to excrete the solute load.

Other Fluid Losses

Water loss through the gastrointestinal tract from stool output is minimal during the first few days of life, particularly in infants with low birthweight. When enteral feeds begin, the water loss in the stool is 5 to 10 mL/kg per day. In a growing infant, the amount of water required for new tissue formation should be considered in the calculation of maintenance fluid requirements. Because infants grow at the rate of 10 to 20 g/kg per day, and new tissue contains 70% water, the maintenance fluid required should provide a net water balance of 10 to 15 mL/kg per day.

Electrolyte Requirements

Maintenance sodium and chloride should not be provided in the first 1 to 2 days of life because of the relatively volume-expanded state of the newborn. Avoidance of sodium supplementation is particularly important in very premature infants, who have increased water losses, and for whom early administration of sodium supplementation is associated with an increased risk of hypernatremia.[43] Sodium supplementation from the 4th to the 14th day of life in premature infants was associated with improved developmental outcomes at age 10 to 13 years compared with a group of premature infants who did not receive supplementation.[2]

Potassium is not provided in parenteral fluid until urinary flow has been established, and normal renal function is ensured. From postnatal days 3 to 7, maintenance sodium, potassium, and chloride requirements are approximately 1 to 2 mEq/kg per day. Beyond the first week of life, 2 to 3 mEq/kg per day or more of sodium and chloride is required to maintain the positive electrolyte balance that is necessary for the formation of new tissue. Because of high urinary sodium losses, premature infants may require 4 or 5 mEq/kg of sodium per day during the first few weeks of life.

Estimating Pathogenic Losses and Deficit Replacement

Many clinical situations require careful estimates of ongoing pathogenic losses and replacement of deficits. Commonly encountered conditions include diarrhea with dehydration, chest tube drainage, surgical wound drainage, and excessive urinary losses from osmotic diuresis. The important guiding principle in managing patients with these conditions is to measure the volume and composition of the pathogenic losses accurately. Electrolyte losses can be calculated by multiplying the volume of fluid loss by the electrolyte content of the respective body fluids (Table 36-3).

Estimating replacement for pathogenic fluid and electrolyte losses can be difficult, particularly in infants who accumulate fluid and electrolytes in static body fluid compartments. This phenomenon, commonly referred to as “third spacing,” occurs in several conditions, including sepsis, hydrops fetalis, hypoalbuminemia, intra-abdominal infections, and after abdominal or cardiac surgery. An infant with necrotizing enterocolitis often accumulates fluid in the mucosal and submucosal tissues of the small and large intestine and in the peritoneal cavity. Under these circumstances, large amounts of fluid, electrolytes, and protein may leak into the interstitial tissue and cannot be accurately quantitated. Because fluid lost into these tissue spaces does not contribute to effective arterial blood volume and circulatory balance in these patients, they may appear edematous even though their intravascular volume is decreased. The most appropriate strategic approach in the management of these

TABLE 36–3 Electrolyte Content of Body Fluids

Fluid Source	Sodium (mmol/L)	Potassium (mmol/L)	Chloride (mmol/L)
Stomach	20-80	5-20	100-150
Small intestine	100-140	5-15	90-120
Bile	120-140	5-15	90-120
Ileostomy	45-135	3-15	20-120
Diarrheal stool	10-90	10-80	10-110

infants is to replenish the extracellular fluid compartments with colloid and crystalloid, as able.

MONITORING FLUID AND ELECTROLYTE BALANCE

Interpretation of key clinical feedback is a crucial part of successful fluid and electrolyte management strategies in newborns. Fluid and electrolyte balance can be achieved by using a meticulous and organized system that obtains pertinent data and applies the physiologic principles outlined in the beginning of this chapter. A careful assessment of clinical indicators of volume status, including heart rate, blood pressure, skin turgor, capillary refill, oral mucosa integrity, and fullness of the anterior fontanelle, is essential. Other pertinent data that must be monitored include body weight, fluid intake, urine and stool output, serum electrolytes, and urine osmolarity or specific gravity.

During the first few days of life, appropriate fluid and electrolyte balance is reflected by a urine output of approximately 1 to 3 mL/kg per hour, a urine specific gravity of approximately 1.008 to 1.012, and an approximate weight loss of 5% in term infants and 15% in premature infants with very low birthweight.[44] Microsampling of serum electrolytes can be done at 8- to 24-hour intervals, depending on illness severity, gestational age, and fluid-electrolyte balance. Extracellular volume depletion is manifest by excessive weight loss, dry oral mucosa, sunken anterior fontanelle, capillary refill greater than 3 seconds, diminished skin turgor, increased heart rate, low blood pressure, elevated blood urea nitrogen, or metabolic acidosis. Serum sodium, which reflects sodium concentration but not sodium content, may be normal, decreased, or increased in states of volume depletion. Bedside monitoring of weight gain, as an indicator of volume status and growth, is essential for monitoring the adequacy of fluid and caloric intake in sick neonates. Beyond the first week of life, infants should gain approximately 20 to 30 g per day.

HYPONATREMIA AND HYPERNATREMIA

Hyponatremia

Hyponatremia, defined as a serum sodium less than 130 mmol/L, is caused by one of three general mechanisms: (1) an inability to excrete a water load, (2) excessive sodium losses, or (3) inadequate sodium intake. Most commonly, sick newborns are unable to excrete a water load because of a decreased effective arterial blood volume preventing the suppression of ADH secretion. Hyponatremia may also occur because of decreased fluid delivery to the distal nephron diluting segments. Two common etiologies of this decreased delivery are decreased GFR caused by acute renal failure and increased proximal tubular fluid and sodium reabsorption associated with volume depletion. Defects in sodium chloride transport in the cortical and medullary ascending limb of the loop of Henle, which is essential in producing an osmotic gradient for distal water absorption via the countercurrent multiplier, also limit the diluting capacity of the nephron. The treatment for hyponatremia varies depending on the underlying etiology. A patient with hyponatremia and volume depletion should receive increased fluids, whereas a patient with oliguric acute renal failure should have fluids restricted. These examples highlight the importance of assessing the neonate's volume status when determining therapy.

COMMON CAUSES OF HYPONATREMIA IN NEONATES

Hyponatremia in a newborn may occur early during the first week of life (early onset) or in the latter half (late onset) of the first month of life. The early-onset form usually reflects free water excess because of either increased maternal free water intake during labor[17] or perinatal nonosmotic release of vasopressin.[33] The latter may be seen in conditions such as perinatal asphyxia, respiratory distress, bilateral pneumothoraces, and intraventricular hemorrhage,[32] or with various medications, including morphine, barbiturates, or carbamazepine. Early-onset hyponatremia may also occur from excess free water administration in the postnatal period and suboptimal sodium intake in oral feeds or parenteral fluids.

Late-onset hyponatremia is most commonly due to negative sodium balance. This condition may occur from either inadequate sodium intake or excessive renal losses because of a high fractional excretion of sodium, particularly in preterm infants of less than 28 weeks' gestation.[45] Uncommonly, free water retention from excessive ADH release, renal failure, or edematous disorders may also contribute to late-onset hyponatremia. Water restriction is necessary to treat hyponatremia related to these disorders.

UNCOMMON CAUSES OF HYPONATREMIA IN NEONATES

Aldosterone is a steroid hormone produced in the adrenal cortex that has a crucial role in maintaining sodium and potassium homeostasis in the kidney. It is produced in response to either volume depletion, via the renin-angiotensin-aldosterone axis, or an increase in serum potassium. Under the influence of aldosterone, apical epithelial sodium channels are inserted on the luminal (urinary) surface, allowing sodium to be reabsorbed down its concentration gradient. Potassium, as the primary intracellular cation, is excreted in return. This process is facilitated further by aldosterone-mediated increase in the activity of basolateral Na^+,K^+-ATPase.[38] Aldosterone also has a role in acid-base homeostasis and promotes hydrogen secretion (see "Acid-Base Management" later) via actions on H^+-ATPase located on the luminal surface of adjacent intercalated cells. Abnormalities in either the production of or the renal responsiveness to aldosterone can result in variable degrees of renal sodium wasting, hyperkalemia, and metabolic acidosis.

Congenital Adrenal Hyperplasia

The most common form of congenital adrenal hyperplasia is complete absence of 21-hydroxylase activity, a key enzyme in the production of aldosterone. Affected girls have ambiguous genitalia at birth because of excess adrenal androgens. Patients typically present with severe hyponatremia, hyperkalemia, and metabolic acidosis at 1 to 3 weeks of age as the result of a salt-losing crisis. Additional laboratory abnormalities typically seen with this disorder include elevated plasma levels of renin, adrenocorticotropic hormone, 17-hydroxyprogesterone, progesterone, and androstenedione; increased urinary 17-ketosteroids; and undetectable serum cortisol levels. Initial treatment is directed at correcting the electrolyte abnormalities. Normal saline or 3% saline should be used to correct the serum sodium to at least 125 mmol/L. Insulin at a dose of 0.1 U/kg with 0.5 g/kg of glucose should be given for serum potassium values exceeding 7 mEq/L. Transcellular shifts of potassium into cells are facilitated further by bicarbonate administration at a dose of 1 or 2 mEq/kg. Concomitant glucocorticoid/mineralocorticoid replacement therapy should be instituted to facilitate normalization of serum electrolytes and to treat the underlying disease. Sodium supplements may be necessary for a prolonged period.

Pseudohypoaldosteronism

Pseudohypoaldosteronism (PHA) refers to a group of disorders characterized by apparent renal tubular unresponsiveness to aldosterone as evidenced by hyperkalemia, metabolic acidosis, and variable degrees of renal sodium wasting. PHA has two major subtypes. Type I usually manifests in infancy with hypotension, severe sodium wasting, and hyperkalemia. Type II (Gordon syndrome) typically manifests in late childhood and adulthood, and is not discussed in detail.[31]

Type I PHA may be primary, inherited as an autosomal recessive or autosomal dominant trait, or secondary, resulting from tubular damage from disorders such as obstructive uropathy. Autosomal dominant type I PHA, previously designated the “renal” type I, is the most common type I PHA. Patients with this form usually present during early infancy with failure to thrive, weight loss, vomiting, dehydration, or shock. A history of polyhydramnios is often present, reflecting excessive fetal renal salt-wasting and polyuria. Sweat and salivary electrolytes are normal in this form of type I PHA. Although it is inherited in an autosomal dominant trait, expression may be variable. The disorder is caused by mutations in the gene encoding the aldosterone (mineralocorticoid) receptor. Treatment involves administration of large quantities of sodium chloride, 10 to 15 mEq/kg per day. Although the defect in salt handling seems to be lifelong, serum sodium levels typically become easier to control by 1 to 2 years of age. Increased dietary sodium intake, maturation of proximal tubular transport of sodium, and improvement in the renal tubular response to mineralocorticoids all may contribute to the clinical improvement over time.

Autosomal recessive type I PHA, previously designated “multiple target organ defects” type I PHA, is a severe, life-threatening systemic disease that affects sodium and potassium handling in the kidney, sweat glands, salivary glands, nasal mucosa, and colon.[14] Patients with this disorder usually present in the newborn period with severe salt wasting and life-threatening hyperkalemia. They also have increased sweat chloride that may mimic the presentation of cystic fibrosis. Patients with autosomal recessive type I PHA have a poorer outcome compared with patients with the autosomal dominant form because of the systemic nature of the disease and complete unresponsiveness to mineralocorticoid effects in multiple organs.

The disease is caused by mutations in one of three subunits of the amiloride-sensitive epithelial sodium channel of the principal collecting tubule cell, resulting in markedly impaired sodium reabsorption and potassium secretion. Sodium chloride supplementation alone often is inadequate in controlling hyperkalemia and metabolic acidosis in these patients. Dietary restriction of potassium intake and the use of rectal sodium polystyrene sulfonate resin (Kayexalate), a sodium-potassium exchange resin, are often required. Indomethacin or hydrochlorothiazide may be necessary to control hyperkalemia and acidosis. These therapies must be continued throughout the child’s lifetime because improvement with age usually does not occur.

Secondary forms of type I PHA are also seen in the newborn period. Partial tubular insensitivity to aldosterone may be seen in patients with unilateral renal vein thrombosis, neonatal medullary necrosis, urinary tract malformations, pyelonephritis, or other tubulointerstitial diseases. Patients with congenital obstructive uropathies, such as posterior urethral valves, may exhibit aldosterone resistance, manifest as a hyperkalemic metabolic acidosis despite relatively intact renal function.

Hypernatremia

Hypernatremia, defined as a serum sodium greater than 150 mmol/L, occurs as the result of increased insensible or urinary water losses, inadequate water intake, or excess sodium administration. Hypernatremia occurring in the first week of life is typically due to increased insensible water losses, often coupled with the excess sodium intake that commonly occurs after resuscitation with sodium bicarbonate. Many other medications can contribute to large “inadvertent” sodium loads, particularly in sick premature infants, including calcium gluconate, gentamicin, dopamine, dobutamine, heparin, and intravenous fluids used to maintain arterial or venous vascular lines.[7] Onset of hypernatremia later in the first month of life usually is due to either excess sodium supplementation or inadequate free water intake.

Excess urinary losses can occur as the result of diabetes insipidus (DI), which is characterized by severe urinary water losses reflecting an inability to produce a concentrated urine. DI may occur as the result of low levels of circulating ADH (central DI), or impaired renal response to ADH (nephrogenic DI). Newborns with this disorder present with polyuria, polydipsia, chronic dehydration, irritability, fever, poor feeding, and growth failure.

Nephrogenic DI can be inherited or occur as the secondary result of processes that cause renal tubular damage. The most common inherited form of nephrogenic DI is caused by mutations in the gene encoding the vasopressin receptor V2R and is inherited as an X-linked recessive disease. Less commonly, autosomal recessive and autosomal dominant forms have been reported, caused by mutations in the AQ2 water channel.[26] Causes of secondary nephrogenic DI include congenital structural disorders such as obstructive uropathy or nephronophthisis, chronic kidney disease, hypercalcemia, and hypokalemia. Treatment of nephrogenic DI includes placement on a low sodium formula to reduce solute intake and resultant obligate water loss associated with solute excretion. Thiazide diuretics are also used to reduce extracellular sodium content, which enhances sodium reabsorption in the proximal tubule and diminishes sodium and water delivery to the distal nephron. Amiloride may also be necessary to reduce urinary potassium losses that may occur with the use of thiazide diuretics. Although prostaglandin inhibitors have been successfully used to treat nephrogenic DI, long-term use of these agents is not recommended because of gastrointestinal, hematopoietic, and renal complications.

Central DI may be due to midline central nervous system malformations, anoxic encephalopathy, cerebral edema, or trauma. Although some ADH secretion may be present in central DI, levels are insufficient to promote appropriate water absorption in the distal nephron. Desmopressin acetate (DDAVP) is effective therapy for this condition, and DDAVP responsiveness can help distinguish central versus nephrogenic causes when the underlying etiology is unclear.

FLUID AND ELECTROLYTE THERAPY IN COMMON NEONATAL CONDITIONS

Perinatal Asphyxia

Renal parenchymal injury from perinatal asphyxia frequently results in acute tubular necrosis, which is commonly accompanied by oliguria or anuria. In the presence of acute renal failure, fluid restriction to amounts equal to urine output plus insensible losses is crucial to avoid volume excess. In a term infant, insensible water losses are approximately 20 to 25 mL/kg per day, and stool loss is minimal. Fluid requirements during the first day of life in an anuric term infant are approximately 30 mL/kg per day. Insensible losses for an anuric premature infant may be as high as 80 mL/kg per day, depending on gestational age. Fluid restriction is often difficult to accomplish when relatively large volumes of intravenous drugs are necessary or when the absence of central venous access limits the concentration of dextrose-containing fluid that can be delivered. High caloric density parenteral nutrition, delivered in as small a volume as possible, is often necessary when fluid restriction is undertaken to avoid fluid overload and water intoxication. When urine production normalizes, fluid intake can be liberalized to reflect urine output and insensible losses.

If the cause of oliguria or anuria is unclear, and the infant is believed to be intravascularly depleted, a test dose of 10 mL/kg body weight of crystalloid or colloid can be given. During the oliguric or anuric phase of acute tubular necrosis, potassium should not be given to avoid hyperkalemia. During the recovery phase of acute tubular necrosis, small infants may experience large urinary sodium and potassium losses, which should be quantitated and replaced.

In severe perinatal asphyxia, the renal parenchymal injury may be severe enough to produce renal failure lasting for several days to weeks, or may be permanent in cases with cortical necrosis. In the presence of hyperkalemia, defined as a serum potassium greater than 7 mEq/L, the cardiac rhythm of the infant should be monitored by continuous electrocardiogram to detect any cardiac arrhythmia. Treatment options for hyperkalemia include insulin, given with glucose; sodium polystyrene sulfonate resin (Kayexalate); sodium bicarbonate, if a metabolic acidosis is present; and peritoneal dialysis. If a significant arrhythmia is present, calcium chloride or calcium gluconate infusion is also indicated to antagonize the toxic effects of hyperkalemia on the cardiac membrane. Although fluid restriction is initiated in infants with perinatal asphyxia even in the absence of acute renal failure, no systematic randomized studies have determined whether this practice alters the long-term outcome for these patients.[20]

Symptomatic Patent Ductus Arteriosus

PDA with left-to-right shunt and pulmonary edema is a common cause of morbidity in preterm infants, particularly infants with respiratory distress syndrome in the first few days of life. Fluid overload during this period is associated with an increased incidence of symptomatic PDA.[5] The precise mechanism by which fluid overload leads to an increased risk of PDA is unclear, but it may be related to the lack of isotonic contraction of body fluids in this group of infants. Although the timing of treatment for PDA, especially with respect to prophylaxis of an asymptomatic PDA, and optimal dosing regimen remain ongoing issues of debate, intravenous indomethacin and ibuprofen remain an important component of medical management of PDA.

Renal insufficiency is an important potential complication of indomethacin use and is due to inhibition of vasodilatory prostaglandins resulting in unopposed renal vasoconstriction. Risk factors for developing renal insufficiency after indomethacin treatment include existing renal or electrolyte abnormalities, maternal exposure to indomethacin used as a tocolytic agent, and chorioamnionitis.[15] Urine output and renal function must be monitored closely during the course of intravenous indomethacin therapy. The lowest possible effective doses of indomethacin should be used, and concomitant administration of other nephrotoxic agents, such as aminoglycosides, should be avoided. Use of ibuprofen for ductal closure is associated with a lower risk of renal insufficiency. (See also Chapter 45.)

Chronic Lung Disease

Infants with chronic lung disease present complex challenges in fluid and electrolyte management. Because of higher basal metabolic rates and increased caloric requirements, the caloric density or volume, or both, of parenteral or enteral feedings needs to be maximized. Care must be taken to provide optimal fluid and nutrient intake without incurring volume overload and worsening pulmonary disease. In addition, therapies used to treat the underlying lung disease—most notably, diuretics—may have significant effects on fluid and electrolyte balance.[19]

Furosemide, a potent loop diuretic, causes a marked increase in urinary sodium, potassium, and hydrogen ion excretion, leading to hypokalemic metabolic alkalosis. Long-term use of this diuretic may also result in enhanced urinary excretion of calcium leading to osteopenia of prematurity, urolithiasis, or nephrocalcinosis. Furosemide should be used with caution in neonates, particularly premature infants, with acute renal failure and infants receiving concomitant aminoglycoside therapy, to avoid complications of ototoxicity. Chlorothiazide, a less potent thiazide diuretic that acts at the distal tubule, also causes a hypokalemic metabolic alkalosis. In contrast to loop diuretics, thiazides decrease urinary calcium excretion. Treatment with spironolactone, a potassium-sparing aldosterone inhibitor, may be associated with hyperkalemia. Strategies used to avoid complications of diuretic use include minimizing diuretic dosages, obtaining serum electrolyte measurements to detect electrolyte imbalance, monitoring urinary calcium excretion (when applicable), and calcium supplementation to prevent osteopenia of prematurity.

PART 2

Acid-Base Management

Katherine MacRae Dell

In this section, normal acid-base homeostasis in neonates is reviewed, and how these processes are influenced during the stages of nephron development is discussed. The diagnostic and therapeutic approach to acid-base disorders is presented, and common acid-base disorders are discussed.

ACID-BASE HOMEOSTASIS IN NEONATES

Normal neonatal metabolism occurs within a tightly controlled extracellular pH ranging from 7.35 to 7.43. Normal growth and development critically depend on this homeostasis, which is threatened in ill term newborns or premature infants. The maintenance of serum pH (i.e., hydrogen ion concentration) within the physiologic range requires two major processes: (1) acute compensation, which is accomplished by rapid acid or base buffering by intracellular and extracellular buffers in response to acute decreases or increases in serum pH, and (2) long-term compensation, which is accomplished by renal excretion of acid or base, including an obligate daily acid load of approximately 1 to 2 mEq/kg per day. Renal and extrarenal homeostatic mechanisms contribute to the maintenance of acid-base balance.

ACUTE COMPENSATION: BODY BUFFER SYSTEMS

After an acute change in serum pH caused by losses or gains of acid or base to the body, intracellular and extracellular buffering mechanisms respond rapidly to return the serum pH to a physiologic level. In response to a decrease in pH, H^+ enters the cell in exchange for K^+ by way of an H^+/K^+ exchanger. H^+ is buffered by intracellular buffers, including hemoglobin, organic phosphates, and bone hydroxyapatite. Conversely, when serum pH increases, H^+ leaves the cell in exchange for K^+. Acute acidosis often results in hyperkalemia, whereas alkalosis is associated with hypokalemia. Intracellular buffering accounts for about 47% of an acute acid load, and can reach even higher levels during more prolonged episodes of acidosis. Much of this buffering capacity is in bone. In disorders characterized by chronic acidosis, increased bone resorption and loss of bone sodium, potassium, calcium, and carbonate occur. These effects on bone partially explain the invariable association of growth failure, a potentially significant issue for premature infants, with acidosis.

The major buffering mechanism in the extracellular fluid (ECF) is mediated by the carbonic anhydrase system, as reflected in the following formula:

$$H^+ + HCO_3^- \overset{CA}{\rightleftharpoons} H_2CO_3 \overset{CA}{\rightleftharpoons} H_2O + CO_2\uparrow$$

Regulation of carbon dioxide (CO_2) excretion by the respiratory system markedly improves the efficiency of this buffering system at physiologic pH. In the presence of carbonic anhydrase (CA), carbonic acid (H_2CO_3) is in equilibrium with CO_2. Addition or increased production of acid results in consumption of bicarbonate (HCO_3^-) and increased H_2CO_3 and CO_2. CO_2 then crosses the blood-brain barrier, resulting in a decrease in pH. This action stimulates central nervous system chemoreceptors, leading to increased respiration and resultant decreased CO_2 concentration within 12 to 24 hours. Similar respiratory compensation occurs in response to an alkali load, which leads to increased HCO_3^- concentration, resulting in hypoventilation and accumulation of CO_2.

Two formulas are particularly useful in understanding and evaluating acid-base disorders. The *Henderson-Hasselbach equation* expresses the relationship of pH, P_{CO_2}, and HCO_3^-:

$$pH = 6.1 + \log [HCO_3^- / (0.03 - P_{CO_2})]$$

where 6.1 is the pK_a of this equation.

The *Winters formula* can be used to predict the appropriate respiratory response (i.e., decrease in P_{CO_2}) to a metabolic acidosis:

$$P_{CO_2} = (1.5 \times HCO_3^-) + 8 \pm 2$$

Respiratory compensation in response to either metabolic acidosis or metabolic alkalosis does not completely normalize the pH. The Winters formula predicts that a decrease in HCO_3^- to 10 mmol/L would result in a decrease in P_{CO_2} to 21 to 25 mm Hg. By the Henderson-Hasselbach equation, the resulting serum pH is 7.22 to 7.29. This is markedly better than the serum pH of 7.02 that would be seen if no respiratory compensation occurred, but is still not within the normal range. With "simple" metabolic acidosis or alkalosis, the respiratory compensation does not fully correct the serum pH. If a serum pH is found to be in the normal range (or higher or lower than predicted), a mixed acid-base disorder, with an added primary respiratory abnormality, should be considered.

LONG-TERM MAINTENANCE OF ACID-BASE BALANCE

Long-term maintenance of a normal serum pH depends on the balance between the production or intake of acid and base and their metabolism or excretion. Foodstuffs contain a small amount of preformed acid, but most of the daily acid load is a product of metabolism. A large proportion consists of CO_2, which is carried to the lung as bicarbonate and carbamino groups bound to hemoglobin and ultimately excreted through respiration. This is termed *volatile* acid. Hypoventilation or hyperventilation leads to either retention or enhanced excretion of CO_2, and results in acidosis or alkalosis. Metabolic activity also produces an obligate nonvolatile acid "load" of approximately 1 to 2 mEq/kg per day. Most of this acid load is sulfuric acid, which results from metabolism of the sulfur-containing amino acids, methionine and cysteine. The remainder consists primarily of incompletely oxidized organic acids, phosphoric acid and hydrochloric acid. Successful maintenance of acid-base balance depends on renal excretion of this daily acid load.

The kidney plays an essential role in maintaining acid-base homeostasis by three major mechanisms:

1. Reabsorption of filtered bicarbonate and excretion of excessive bicarbonate in response to metabolic alkalosis
2. Excretion of the obligate daily acid load and any additional acid load from pathogenic processes, such as lactic acidosis related to sepsis or bicarbonate loss from diarrhea
3. Compensation for changes in serum pH that result from primary respiratory disorders

Bicarbonate reabsorption occurs primarily in the proximal tubule, where 60% to 80% of the filtered bicarbonate load is reabsorbed. Bicarbonate is not reabsorbed via a specific transporter. Instead it is reabsorbed via an indirect mechanism. Bicarbonate present in the lumen is first buffered by H^+ that is secreted in exchange for sodium via a Na^+/H^+ exchanger located on the luminal membrane of proximal tubular cells (Fig. 36-4). Through the actions of carbonic anhydrase, CO_2 and H_2O are produced. CO_2 and H_2O diffuse into the cell, where HCO_3^- is regenerated and reabsorbed across the basal cell membrane in exchange for chloride. H^+ is also regenerated, making it available again for buffering of additional filtered bicarbonate. The net effect is that for every H^+ secreted, one molecule of filtered bicarbonate is reabsorbed.

Although proximal tubule bicarbonate reabsorption is essential in preventing bicarbonate wasting, no net H^+ excretion occurs in this process. Instead, excretion of the daily acid load is accomplished by two mechanisms: ammoniagenesis and production of titratable acids. Ammoniagenesis occurs in the proximal tubule (see Fig. 36-4), via the metabolic processing of glutamine produced in the liver. In the proximal tubule cell, glutamine is converted to ammonium (NH_4^+), which is secreted into the lumen in exchange for Na^+. Deamination of glutamine also produces α-ketoglutarate, which buffers H^+. Through the actions of the intracellular carbonic anhydrase system, this process eventually results in the production of intracellular HCO_3^-, which can be reabsorbed across the basal membrane of the cell with Na^+. NH_4^+ secretion is the metabolic equivalent to H^+ excretion.

The remainder of acid secretion occurs in the cortical and medullary collecting tubule. H^+ is secreted into the collecting tubule against its pH gradient by H^+-ATPases located on the luminal membrane. This process is influenced by the luminal and peritubular pH, distal sodium delivery, and aldosterone. Secreted H^+ titrates filtered anions, including phosphates and sulfates, producing titratable acids (Fig. 36-5). The collecting tubule also secretes ammonia from the medullary interstitium where is it buffered by H^+ to produce NH_4^+. Titratable acid formation and ammonia buffering require an acidic environment for protonation to occur. In addition to providing a source of H^+ for buffering, distal H^+ secretion is important in maintaining an acidic urine (pH of 4.5 to 5.0).

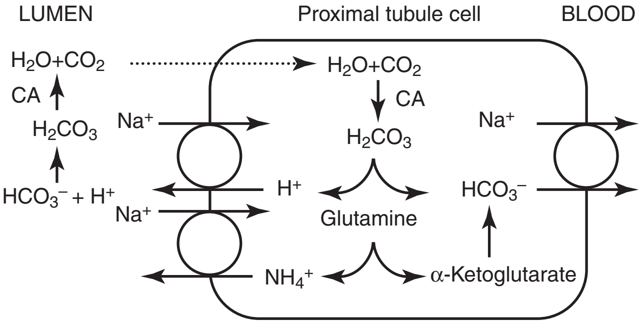

Figure 36–4. Schematic drawing of proximal tubular HCO_3^- reabsorption and ammoniagenesis. See text for explanation. CA, carbonic anhydrase.

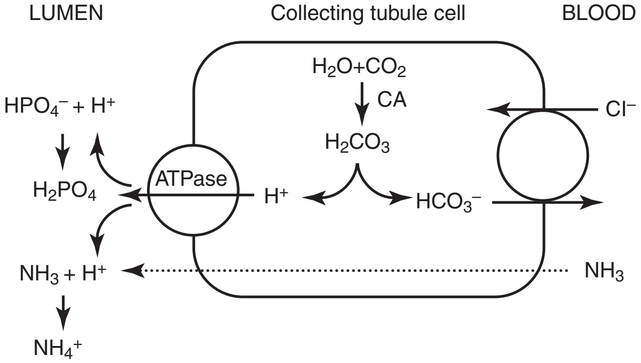

Figure 36–5. Schematic drawing of distal urinary acidification mechanisms. CA, carbonic anhydrase.

The net acid excretion by the kidney is equal to the sum of titratable acids plus ammonium minus any filtered bicarbonate that is not reabsorbed. During steady-state, total acid secretion equals the production of acid from diet and metabolism. In response to an acid load, ammoniagenesis can increase dramatically because of enhanced production of glutamine by the liver. Ammoniagenesis is stimulated by hypokalemia and inhibited by hyperkalemia. In contrast, titratable acids are relatively fixed in their production except in instances of diabetic ketoacidosis, in which the ketone bodies themselves can form titratable acids. Alternatively, the kidney has the capacity to alter HCO_3^- reabsorption in response to changes in the filtered load of bicarbonate, further minimizing changes in pH.

DEVELOPMENTAL ASPECTS OF ACID-BASE PHYSIOLOGY

Although nephron formation is complete by 34 weeks of gestation, maturation and functional changes of the nephron continue during the first year of life. The relative immaturity of the kidney, which is more pronounced in preterm infants, affects basal acid-base status and the response to additional acid and alkali loads.[25] During the initial 24 to 48 hours of life, acid-base balance is influenced by the degree of perinatal stress and environmental factors such as temperature and diet.[46] Between 7 and 21 days of life, neonates are in a state of mild metabolic acidosis. In some infants, blood pH may decrease to less than 7.25, or base deficit may exceed 8 mEq/L.[41]

The causes of this metabolic acidosis in neonates are multifactorial. The threshold for bicarbonate reabsorption in the proximal tubule is lower in neonates, especially premature infants, compared with adults, so that neonates tend to “waste” bicarbonate at a lower blood HCO_3^- concentration (15 to 21 mEq/L). Low GFRs, particularly in premature or stressed neonates, decrease the availability of phosphates and other buffers, decreasing the formation and excretion of titratable acids. Tubular immaturity results in reduced tubular secretory surface for organic acid secretion, diminished number of organic acid transport sites per unit area of renal tubular surface, and diminished energy available for organic acid transport. Premature infants are also unable to acidify their urine maximally at birth, exhibiting a minimal urine pH of 6, in contrast to full-term neonates and adults whose urine pH may reach 4.5. The ability of premature infants to acidify their urine maximally and to excrete an acid load correlates with gestational age. By 6 weeks of age, the capacity of premature and term infants to excrete hydrogen ions matures to permit maximal acidification.

HCO_3^- conservation and net acid excretion are diminished in neonates because of the immaturity of the neonatal kidney. This is particularly true for premature infants of less than 34 weeks’ gestation because of incomplete nephrogenesis. These limitations not only account for decreased baseline serum bicarbonate levels, but also limit the ability of neonates to respond to additional stresses, particularly acid loading. Renal control of acid-base homeostasis does not reach adult levels of function until approximately 2 years of age.

DIAGNOSTIC APPROACH TO DISORDERS OF ACID-BASE BALANCE

In generating a differential diagnosis of an acid-base abnormality, it is helpful to ask the following three questions:

1. What is the primary abnormality?
2. What is the secondary compensation?
3. Is the compensation appropriate?

The acid-base abnormality alone does not indicate if it is the primary disorder or a response to the primary disorder. A low serum bicarbonate level indicating metabolic acidosis could be due to a primary metabolic acidosis or could represent a metabolic compensation for a primary respiratory alkalosis. Conversely, elevated serum bicarbonate could be a reflection of a primary metabolic alkalosis or a response to a primary respiratory acidosis. To distinguish the primary process from the secondary compensation, it is necessary to know the plasma pH, serum bicarbonate level, and CO_2 level. In addition to simple respiratory or metabolic acid-base disorders, “mixed” (combined) disorders may be seen in which more than one primary process is present. Mixed disorders should be considered when the expected compensation falls out of the expected range.

The nomogram presented in Figure 36-6 can aid in the diagnosis of simple and mixed acid-base disorders. It shows the 95% confidence limits of the expected compensatory response to a primary metabolic or respiratory acidosis or alkalosis. If the compensatory change in either P_{CO_2} or HCO_3^- falls beyond these limits (i.e., outside of the shaded region for each disorder), a combined disorder is present. Consider a newborn with pH of 7.17, P_{CO_2} of 34 mm Hg, and HCO_3^- of 12 mEq/L. The acidic pH and low serum HCO_3^- (normal neonatal value is approximately 22 mEq/L) suggest a primary metabolic acidosis. When the values for pH, HCO_3^-, and P_{CO_2} are plotted on the nomogram, however, the convergence point falls out of the range for a simple metabolic acidosis, suggesting the possibility of a superimposed respiratory acidosis. To delineate this further, one can estimate the expected compensation (i.e., a respiratory alkalosis) based on the values presented in Table 36-4 or, alternatively, the Winters formula (see earlier). With a decrease in serum HCO_3^- from 22 mEq/L to 12 mEq/L, P_{CO_2} should decrease by 12.5 mm Hg. The estimated compensation would result in a

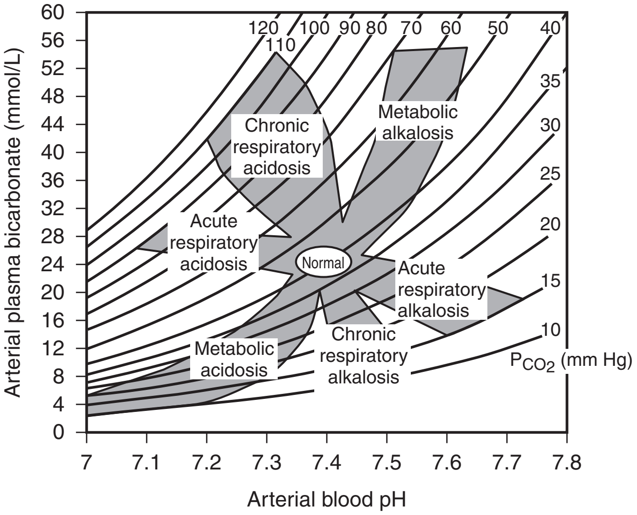

Figure 36–6. Acid-base map showing 95% confidence limits for compensatory responses. *(From Cogan MG et al: In Brenner BM et al, editors:* The kidney, *Philadelphia, 1986, Saunders, p 462.)*

TABLE 36–4 Expected Compensation in Acid-Base Disorders

Respiratory	**ΔP_{CO_2}**		**ΔHCO_3^-**
Acute acidosis	1 mm Hg ↑	→	↑ 0.1 mEq/L
Acute alkalosis	1 mm Hg ↓	→	↓ 0.25 mEq/L
Chronic acidosis	1 mm Hg ↑	→	↑ 0.5 mEq/L
Chronic alkalosis	1 mm Hg ↓	→	↓ 0.5 mEq/L
Metabolic	**ΔHCO_3^-**		**ΔP_{CO_2}**
Acidosis	1 mEq/L ↓	→	↓ 1.25 mm Hg
Alkalosis	1 mEq/L ↑	→	↑ 0.2-0.9 mm Hg

P_{CO_2} of 27 mm Hg. Similarly, the Winters formula predicts a compensatory P_{CO_2} of 24 to 28 mm Hg. The higher than expected P_{CO_2} confirms the presence of a superimposed primary respiratory acidosis.

BASIC PRINCIPLES OF THERAPY

Metabolic Acidosis

Metabolic acidosis is a common problem in critically ill neonates that results from either excess acid production or increased loss of base. Box 36-1 lists common causes of metabolic acidosis in neonates. Calculation of the anion gap allows differentiation into two groups. Increased anion gap metabolic acidosis is caused by the addition of exogenous acids (e.g., salicylates) or increased production of endogenous acids (e.g., lactic acid). In neonates, an increased anion gap is usually due to increased production of endogenous acids, such as lactic acidosis in patients with sepsis or toxic metabolites in patients with inborn errors of metabolism. Increased anion gap metabolic acidosis is associated with a normal serum chloride.

In contrast, a normal anion gap metabolic acidosis is due to either bicarbonate loss in the urine (proximal renal tubular acidosis [RTA]) or the stool or the inability to excrete acid because of a defect in distal nephron function (distal RTA). In this disorder, the serum chloride is elevated. Correction of the underlying cause is the most important therapeutic measure in the management of metabolic acidosis. The dose of alkali required to treat metabolic acidosis in newborns ranges from 1 mEq/kg per day for mild base deficits to 5 to 8 mEq/kg per day for more severe base deficits, such as seen in proximal RTA. Dialysis may be required when acid production is severe, such as in lactic acidosis, renal failure, or severe inborn errors of metabolism.

Administration of alkali, such as bicarbonate, has several potential adverse effects, including volume overload, hypernatremia, decreased oxygen delivery to the brain secondary to shifts in the hemoglobin dissociation curve, increased P_{CO_2}, and a paradoxical intracellular acidosis as CO_2 diffuses into cells.[34] Bicarbonate administration should be reserved for severe acidosis, with a pH less than 7.2, the level below which cardiac output may be compromised. Aggressive alkali therapy is necessary in cases of RTA to prevent growth failure.

BOX 36–1 Common Causes of Metabolic Acidosis in Neonates

INCREASED ANION GAP

Lactic acidosis

- Hypoxemia, shock, sepsis
- Inborn errors of carbohydrate or pyruvate metabolism
- Pyruvate dehydrogenase deficiency
- Pyruvate carboxylase deficiency
- Mitochondrial respiratory chain defects
- Renal failure

Ketoacidosis

- Glycogen storage disease (type I)
- Inborn errors of amino acid or organic acid metabolism

NORMAL ANION GAP

- Bicarbonate loss: acute diarrhea; drainage from small bowel, biliary, or pancreatic tube; fistula drainage; bowel augmentation cystoplasty; ureteral diversion with bowel
- Renal tubular acidosis
- Mineralocorticoid deficiency
- Administration of Cl^--containing compounds: arginine HCl, HCl, $CaCl_2$, $MgCl_2$, NH_4Cl hyperalimentation, high-protein formula
- Carbonic anhydrase inhibitors
- Dilution of extracellular fluid compartment

Adapted from Brewer E: Disorders of acid-base balance, *Pediatr Clin North Am* 37:429, 1990.

Metabolic Alkalosis

Metabolic alkalosis is generated by one of three general mechanisms: (1) loss of acid, such as hydrochloric acid loss with vomiting; (2) ingestion of base, such as sodium bicarbonate administration during resuscitation; or (3) contraction of the extracellular volume, with loss of fluid containing more chloride than bicarbonate. Box 36-2 lists common causes of metabolic alkalosis in neonates.[9]

Although the kidney is usually very effective in excreting excess alkali, several conditions maintain a metabolic alkalosis when it is generated. Extracellular volume depletion limits bicarbonate excretion by several mechanisms. The decrease in GFR reduces the filtered load of bicarbonate, and the bicarbonate that is filtered is rapidly reabsorbed in the proximal tubule as a result of avid sodium reabsorption. Volume depletion also stimulates renin-angiotensin system–mediated release of aldosterone, which leads to an increase in distal renal tubular absorption of sodium and excretion of H^+ and potassium. Other states of hyperaldosteronism, such as excess production of endogenous mineralocorticoids or administration of exogenous steroids, lead to enhanced distal renal tubular excretion of H^+ and potassium. Potassium depletion also maintains a metabolic alkalosis by stimulating renal ammoniagenesis and inhibiting movement of H^+ out of the cell. Chloride depletion or respiratory acidosis, as evidenced by an elevated P_{CO_2}, can also maintain a metabolic alkalosis.

Therapy for metabolic alkalosis consists of correction of the underlying disorder. Alkalosis resulting from volume depletion typically improves with saline administration and

BOX 36–2 Common Causes of Metabolic Alkalosis in Neonates

- Acid loss: vomiting (e.g., pyloric stenosis), nasogastric suction
- Diuretics
- Chloride deficiency: chronic chloride-losing diarrhea, Bartter syndrome, low-chloride formula, loss via skin secondary to cystic fibrosis
- Administration of alkali: bicarbonate, lactate, acetate, citrate

potassium repletion. Agents such as arginine hydrochloride, ammonium hydrochloride, and dilute hydrochloric acid should be used only in rare situations because life-threatening complications may occur, such as severe acidosis or a paradoxical intracellular alkalosis. Patients with a contraction alkalosis, which is commonly seen in infants with bronchopulmonary dysplasia, congenital heart disease, or other diseases requiring long-term diuretic therapy, typically have significant deficits of potassium and chloride. These deficits should be replaced because serum potassium levels may underestimate significantly the intracellular deficit. Oral and intravenous potassium supplementation may be required to correct significant total body potassium deficits. Although the long-term complications of chronic metabolic alkalosis are unknown, prolonged pH greater than 7.6 may increase the risk for sensorineural hearing loss.[23]

Respiratory Acidosis and Alkalosis

Respiratory acidosis results from any disorder with decreased alveolar ventilation, resulting in retention of CO_2. In neonates, this condition is usually due to respiratory distress syndrome, meconium aspiration syndrome, pulmonary infections, or congenital diaphragmatic hernia. Correction of the underlying cause of respiratory acidosis is essential and frequently requires the use of assisted ventilation to increase excretion of volatile acid (CO_2). Administration of alkali to correct acidemia caused by a primary respiratory acidosis is generally inappropriate. The resultant increase in serum bicarbonate levels (and serum pH) promotes hypoventilation and a further increase in P_{CO_2}, exacerbating the respiratory acidosis. In instances where a mixed acid-base disorder is present (i.e., a primary respiratory acidosis and a primary metabolic acidosis), bicarbonate administration should be used with caution, and assisted ventilation is typically required.

Respiratory alkalosis is rare in neonates; however, it may occur during excessive assisted ventilation or during central hyperventilation secondary to serious central nervous system disease such as intraventricular hemorrhage. Patients with respiratory alkalosis who are dependent on ventilators are treated easily by adjusting the assisted ventilation settings. A search for underlying causes of central hyperventilation is necessary in other patients.

SPECIFIC ACID-BASE DISORDERS THAT MAY MANIFEST IN THE NEONATAL PERIOD

Renal Tubular Acidosis

RTA is a disorder characterized by a normal anion gap metabolic acidosis, and is the sequela of either impaired reabsorption of bicarbonate or impaired urinary acidification/H^+ ion excretion.[40] RTA may be the result of an inherited defect in the renal handling of H^+ ion or bicarbonate.[37] More commonly, it is secondary to tubular damage from various causes, such as medications or obstructive uropathy. There are three main forms of RTA: type I (distal), type II (proximal), and type IV (hyperkalemic) (Box 36-3). Each form of RTA has a distinct pathophysiology and characteristic serum and urinary laboratory findings.[10]

BOX 36–3 Classification of Renal Tubular Acidosis

TYPE I (DISTAL)
- Primary (autosomal dominant or recessive; sporadic)
- Secondary, associated with other renal disorders
  - Obstructive uropathy
  - Hypercalciuria/nephrocalcinosis
- Secondary, associated with acquired or other hereditary diseases
  - Osteopetrosis
  - Sickle cell anemia
  - Hereditary elliptocytosis
  - Marfan syndrome
  - Primary biliary cirrhosis
- Secondary, associated with drugs or toxins (e.g., amphotericin B)

TYPE II (PROXIMAL)
- Primary (familial or sporadic)
- Fanconi syndrome
  - Primary
  - Cystinosis
  - Tyrosinemia
  - Oculocerebral renal syndrome (Lowe syndrome)
  - Hereditary fructose intolerance
  - Wilson disease

TYPE IV (HYPERKALEMIC)
- Pseudohypoaldosteronism
  - Renal immaturity
  - Obstructive uropathy
  - Potassium-sparing diuretics
- Chloride shunt
- Hyporenin hypoaldosteronism
- Medications (e.g., cyclosporine)

Adapted from Brewer E: Disorders of acid-base balance, *Pediatr Clin North Am* 37:429, 1990.

Type I (distal) RTA results from diminished distal H^+ secretion. Patients with distal RTA often present in the newborn period or during early infancy with lethargy, polyuria, vomiting, dehydration, and failure to thrive. Distal RTA is usually accompanied by hypokalemia because potassium is secreted in lieu of H^+ to maintain electronegativity. Concomitant hypercalciuria and hypocitraturia predispose patients to the development of nephrocalcinosis and nephrolithiasis.

Distal RTA can occur as a sporadic form, although several well-characterized inherited forms have been described. In each instance, the genetic defect results in impairment of a specific component of the distal acidification mechanisms (see Fig. 36-5). Autosomal recessive and autosomal dominant forms have been described.[37] Acquired forms of type I RTA can also occur as the result of tubular injury. Certain medications cause damage to the distal nephron and result in backleak of H^+ from the lumen. Amphotericin toxicity is a classic example of this “gradient defect” form of acquired distal RTA. In addition, congenital lesions, most notably obstructive uropathies, may cause secondary RTA because of tubular damage from obstruction or infections.

The diagnosis of suspected distal RTA should be considered in any infant with a urinary pH that is greater than 6.5 in the presence of a non-anion gap metabolic acidosis. Conversely, a urine pH of 5.5 or less indicates that distal acidification mechanisms are intact and effectively rules out distal RTA. If the diagnosis is unclear, two different methods have been proposed to assess the distal acidification mechanisms formally. Measurement of the urine-to-blood P_{CO_2} gradient can be used to assess distal tubular urinary acidification after bicarbonate loading. After bicarbonate loading in the presence of normal distal tubular acidification, P_{CO_2} should be at least 20 mm Hg greater than the blood P_{CO_2}. With normal function, secreted H^+ combines with bicarbonate to form carbonic acid and ultimately CO_2, leading to a gradient in P_{CO_2} between urine and blood. In distal RTA, this gradient is diminished because of diminished H^+ secretion.[24] Alternatively, the urine anion gap ($= Na^+ + K^+ - Cl^-$) indirectly assesses the amount of urine ammonium. A positive value suggests a defect in urine ammonium excretion and deficient urinary acidification.[22]

Although primary distal RTA is a permanent defect, the prognosis for growth and the prevention of renal insufficiency are satisfactory when the condition is correctly treated. Therapy for distal RTA in infancy consists of the administration of alkali, usually in the form of an alkali-containing liquid such as Bicitra®. The typical dose is 2 to 3 mEq/kg per day. Maintenance of normal blood pH and serum bicarbonate maximizes the opportunity for normal growth.

Type II (proximal) RTA is caused by a decrease in the threshold tubular maximum for HCO_3^- reabsorption in the proximal tubule, resulting in HCO_3^- wastage. The tubular maximum is decreased to approximately 15 mEq/L, so reabsorption of bicarbonate does not occur until the serum levels decrease to less than this value. The loss of HCO_3^- is often large because 60% to 80% of the filtered HCO_3^- is normally reabsorbed in the proximal tubule. Distal urinary acidification is normal, and patients can appropriately acidify the urine ($pH \leq 5.5$) when plasma HCO_3^- levels are less than 14 to 15 mEq/L. An increase in plasma HCO_3^- beyond the capacity of the proximal tubule results in HCO_3^- wastage and an alkaline urine pH of 7.6 or greater. Isolated inherited forms of proximal RTA occur rarely and can be inherited as an autosomal recessive (with ocular abnormalities) or autosomal dominant trait.[37]

More commonly, proximal RTA is a component of Fanconi syndrome, a disorder of global proximal tubule dysfunction. In addition to bicarbonate wasting, patients with Fanconi syndrome exhibit tubular wasting of sodium, potassium, glucose, phosphorus, and amino acids. Fanconi syndrome is seen in many inherited metabolic disorders, including Lowe syndrome, galactosemia, tyrosinemia, and hereditary fructose intolerance.[10] Patients with proximal RTA typically require larger amounts of bicarbonate supplementation than patients with distal RTA. Dosages of 10 mEq/kg or more per day may be required because of excessive HCO_3^- wastage.

As previously discussed, neonates display a mild degree of proximal RTA because of an altered threshold for proximal tubular HCO_3^- reabsorption, with maintenance of plasma HCO_3^- of 20 to 24 mEq/L in full-term neonates and 15 to 24 mEq/L in preterm infants. Over the first year of life, the tubular maximum for HCO_3^- increases to adult levels as the proximal tubule elongates and transport function matures. Some infants show delayed maturation that results in a persistent proximal RTA, which usually resolves by 5 or 6 years of age.

Type IV (hyperkalemic) RTA is characterized by impaired ammoniagenesis as the result of hyperkalemia. Hyperkalemia results from abnormalities in aldosterone production or from altered tubular sensitivity to aldosterone. Disorders associated with abnormalities in mineralocorticoid production (e.g., congenital adrenal hyperplasia) or responsiveness (i.e., inherited or acquired pseudohypoaldosteronism) have been discussed earlier in this chapter. The symptoms of type IV RTA in infancy include dehydration and symptoms related to hyperkalemia. Laboratory abnormalities include a non-anion gap metabolic acidosis, hyperkalemia, elevated urine sodium, and diminished urine potassium. Therapy for type IV RTA consists of mineralocorticoid supplementation in conditions characterized by a deficiency of aldosterone. Treatment of hyperkalemia may reverse many of the abnormalities; however, alkali supplementation is generally required in patients with end-organ resistance to aldosterone. The need for such supplementation seems to diminish by age 5, possibly because of further maturation of the kidney.

Late Metabolic Acidosis of Prematurity

In 1964, Kildeberg[21] first used the term *late metabolic acidosis of prematurity* to describe a group of otherwise healthy premature infants 1 to 3 weeks old who were characterized by mild to moderate acidosis and decreased growth. All infants were receiving cow's milk formula, which provided 3 to 4 g of protein per kilogram of body weight per day.[47] Net acid excretion was increased in these infants compared with the normal control group. This observation suggests that excessive protein content of cow's milk formula results in endogenous acid production beyond the excretory capacity of the premature kidney, which is limited by urinary bicarbonate losses and reduced phosphate excretion.

Kalhoff and colleagues[18] also described a decrease in renal net acid excretion in infants with low birthweight and examined the effect of bicarbonate supplementation. When randomly assigned to control or bicarbonate therapy groups, infants in the control group who had a persistent urine pH less than 5.4 for 7 days showed a significant decrease in weight gain and a tendency toward decreased nitrogen assimilation. In recent years, metabolic acidosis seems to be less common, which may be explained by a lower protein intake in premature infants. When metabolic acidosis occurs, it is often self-limited and resolves with further renal maturation. Studies suggest that alkali therapy may not benefit growth in this situation.[41]

Neonatal Bartter Syndrome

Bartter syndrome is an inherited disorder characterized by hypokalemia, hypochloremia, and metabolic alkalosis that is often associated with failure to thrive and recurrent episodes of dehydration. It is due to obligate and uncontrolled renal losses of sodium, potassium, and chloride. Currently, there are three clinically and genetically distinct variants of this syndrome, including antenatal Bartter syndrome, "classic" Bartter syndrome, and Gitelman syndrome.[11]

The antenatal variant is the most severe form and manifests in the neonatal period with dehydration, a history of polyhydramnios, and dysmorphic facies characterized by triangular facies, protruding ears, strabismus, and a drooping mouth. Patients typically have elevated urinary calcium excretion, elevated urinary prostaglandin E levels, nephrocalcinosis, and normal serum magnesium levels. This form of Bartter syndrome is inherited as an autosomal recessive trait and is caused by mutations in genes encoding the rectifying potassium channel (ROMK) or the Na^+-K^+-2 Cl^- cotransporter (NKCC2). Both of these transporter proteins are located in the thick ascending loop of Henle and are required for sodium and chloride reabsorption in that nephron segment. Treatment includes the use of indomethacin to inhibit prostaglandin production and aldosterone production, potassium supplementation, and maintenance of adequate intravascular volume. Persistent hypokalemia and nephrocalcinosis rarely leads to chronic renal insufficiency as a result of progressive tubulointerstitial disease.[36]

CHAPTER 37

Diagnostic Imaging

Carlos J. Sivit

Diagnostic imaging is instrumental in the evaluation of infants and neonates with medical and surgical conditions. Therefore, an understanding of the appropriate imaging approach to common neonatal pathologic conditions and the spectrum of imaging findings associated with such conditions is essential to maximize the value of the examination. Imaging also plays an important role in the monitoring of indwelling catheters and tubes in such patients. This chapter is organized by organ system and discusses the imaging approach to common neonatal conditions. It also details the spectrum of imaging appearances of common neonatal abnormalities and emphasizes normal variants that may mimic disease.

CHEST

Respiratory distress in the newborn can stem from a variety of causes, and clinical assessment alone may not be able to differentiate them. Pulmonary disease is the most important cause of morbidity in preterm neonates, whose lungs are often physiologically and morphologically immature. Chest radiography plays an important role in the assessment of cardiac and pulmonary pathology in the neonate and young infant. It is usually the initial examination of choice in the evaluation of suspected cardiopulmonary disease.

A large number of chest radiographs are obtained in many preterm infants with severe respiratory distress. As young children have greater radiosensitivity than older children and adults, there is concern regarding the potential long-term effects of low-dosage diagnostic radiation. Therefore, steps should be taken to minimize radiation exposure. These include careful beam collimation, gonadal shielding, and avoidance of repeat or unnecessary examinations.

It is also important to ensure proper patient positioning, as rotation will distort the image and make evaluation of cardiac and pulmonary pathology difficult. Portable chest radiographs are obtained in the anteroposterior (AP) view with the infant lying supine. The arms should be extended above the head, and the thighs should be immobilized. With proper positioning, the radiograph should demonstrate symmetry of the clavicles and ribs and a midline appearance of the trachea. In addition, extraneous objects including electrodes and leads should be removed from the field of view whenever possible, as they can obscure abnormalities on the radiograph.

Additional imaging modalities can be used to evaluate specific neonatal chest abnormalities. Sonography is useful in the assessment of diaphragmatic motion and pleural fluid. Important advantages of sonography are that it can be performed at the bedside and that it requires no exposure to ionizing radiation. Cross-sectional imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is useful for more surgical and medical treatment planning of more complex thoracic conditions. CT can be used to evaluate parenchymal or mediastinal masses or cysts, as it allows more precise delineation of anatomic structures. MRI is useful in the evaluation of complex congenital heart conditions and vascular rings.

Normal Chest

Familiarity with the normal appearance of the newborn chest and the spectrum of radiographic abnormalities associated with common pathologic conditions enhances the diagnostic yield of the examination. The normal lungs appear primarily radiolucent and symmetric in volume. The pulmonary vessels are seen as branching, linear shadows that taper in size as they extend from the hilum to the lung periphery. Normal vessels decrease in size and number in the lateral one half of lung and are not visualized in the lung periphery. The pleural space is normally empty and collapsed. It is visualized only when it contains fluid or air or is thickened. The heart borders should be distinct, and the diaphragm should be outlined clearly against the lung. The normal cardiac diameter on an AP radiograph should be less than 60% of the thoracic diameter (cardiothoracic ratio). The normal thymus is visible in most newborns. It is extremely variable in size and shape. It typically demonstrates "wavy" undulations of the lateral borders. The thymus often overlies and obscures a portion of the heart, producing the appearance of a large heart (Fig. 37-1). It is composed of two asymmetric lobes and therefore may have an asymmetric appearance at chest radiography (Fig. 37-2).

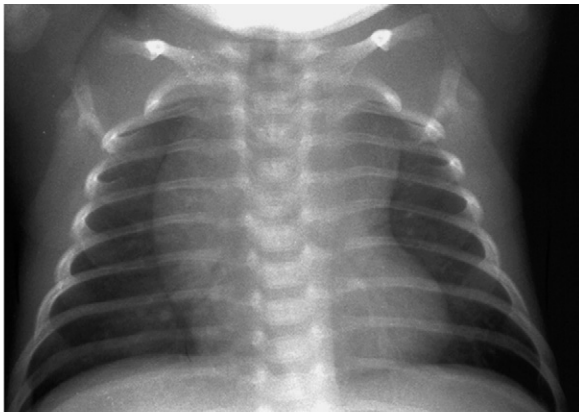

Figure 37–1. Normal thymus. Anteroposterior chest radiograph demonstrates a symmetrically enlarged thymus resulting in a widened mediastinum.

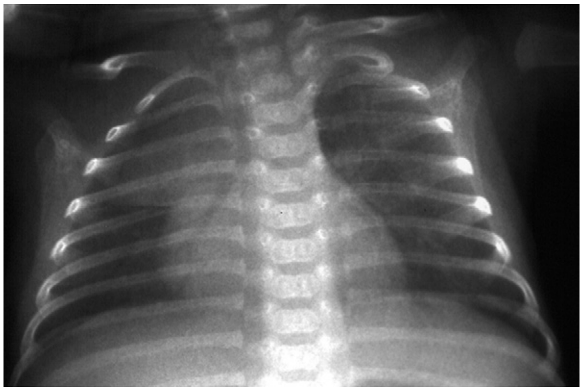

Figure 37–2. Normal thymus. Anteroposterior chest radiograph demonstrates an asymmetrically enlarged right lobe of the thymus.

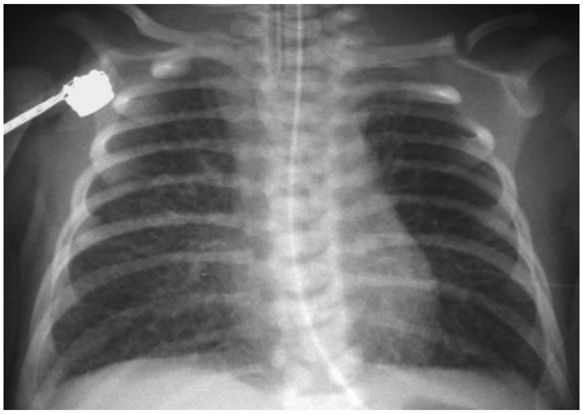

Figure 37–3. Mild surfactant deficiency disease. Anteroposterior chest radiograph demonstrates diffuse ground-glass opacities. Note that some normal pulmonary vessels are still visualized. In addition, the heart borders and diaphragm are well seen.

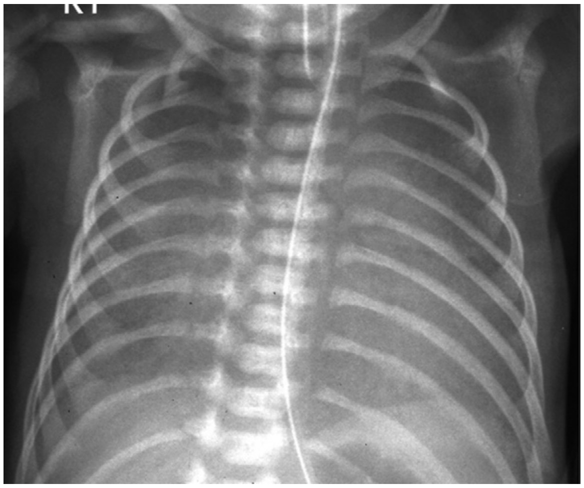

Figure 37–4. Severe surfactant deficiency disease. Anteroposterior chest radiograph demonstrates diffuse ground-glass opacities. Note that the heart borders and diaphragm are silhouetted.

Respiratory Disease: Medically Treated Causes

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS), also referred to as surfactant deficiency disease, is the most common cause of respiratory distress in the premature infant. It is a leading cause of death in premature infants. The inadequate production of surfactant because of the prematurity of type II pneumocytes triggers a cascade leading to decreased alveolar distensibility, capillary leak edema, noncompliant lungs, and respiratory distress.

The typical radiographic appearance of RDS reflects the generalized alveolar collapse and includes a finely granular or ground-glass pattern with diminished lung volumes. The severity of radiographic disease is quite variable and usually correlates with the severity of clinical disease. Mild radiographic disease is characterized by a finely granular pattern that allows visualization of normal vessels (Fig. 37-3), whereas severe disease results in silhouetting of the heart borders and diaphragm (Fig. 37-4). Peripheral air bronchograms may be seen in the lung bases, particularly with severe disease. This finding results from air in the bronchi being visualized against a background of alveolar collapse. The distribution of disease is usually diffuse and symmetric; however, patchy or asymmetric disease may be seen. The radiographic changes associated with RDS are often seen immediately after birth but can also develop over the first 6 to 12 hours of life. The radiographic abnormalities related to uncomplicated RDS should resolve by the time the neonate is 3 to 4 days old.

Chest radiography can be used to help assess the effectiveness of surfactant replacement therapy in infants with RDS.[11,16] Typically, improvement in the appearance of the lungs is rapid and uniform after surfactant administration. In 80% to 90% of neonates treated with surfactant, improvement occurs in one or both lungs. When there is a partial response, the improvement may be asymmetric or even restricted to one lung. Explanations for asymmetric radiographic improvement following surfactant therapy include (1) maldistribution of surfactant, (2) insufficient surfactant, and (3) regional differences in lung aeration before surfactant treatment. The absence of radiographic improvement after surfactant administration is a poor prognostic sign.

Complications can result from the high distending pressures that may be required in the treatment of RDS. Alveolar rupture from overdistention results in pulmonary interstitial emphysema. The radiographic appearance of pulmonary interstitial emphysema includes distinct rounded or linear thoracic lucencies representing air in the perivascular sheath (Fig. 37-5). The abnormalities may be diffuse or focal. Focal air collections (pseudocysts) may also form in the interstitium of the lung. After alveolar rupture, air can also track along the perivascular sheath into the mediastinum or the pleural space, resulting in a pneumomediastinum or pneumothorax. Radiographic signs of pneumomediastinum include (1) lateral displacement of the mediastinal pleura (Fig. 37- 6); (2) continuous diaphragm sign; and (3) superior elevation of the thymus, which is referred to as the *thymic sail sign* (Fig. 37-7). Radiographic findings of pneumothorax include (1) increased thoracic lucency (Fig. 37-8), (2) identification of the visceral pleural line, (3) increased sharpness of a hemidiaphragm, and (4) deep sulcus sign (Fig. 37-9). Lateral decubitus or cross-table lateral radiographs can be useful in the detection of small pneumothoraces. Large pneumothoraces can produce tension, resulting in a shift of mediastinal structures.

Tube and line malpositions are other frequent complications in neonates. An important function of routine chest and abdominal radiographs in neonates is monitoring endotracheal tube position and various arterial and venous catheters. Catheter malpositions are frequent and should be scrutinized on all radiographs. The endotracheal tube tip should be below the inferior margin of the clavicles and above the carina. The umbilical venous catheter tip should be at the right atrial/inferior vena cava junction. The umbilical arterial catheter tip should be below the aortic arch, which is typically at T5, and above the celiac axis, which typically originates at T12-L1. Umbilical catheters should follow a straight course as they extend cephalad. Catheter curvature or angulation usually indicates catheter malposition. Percutaneously placed catheters should be at the right atrial/superior vena cava junction.

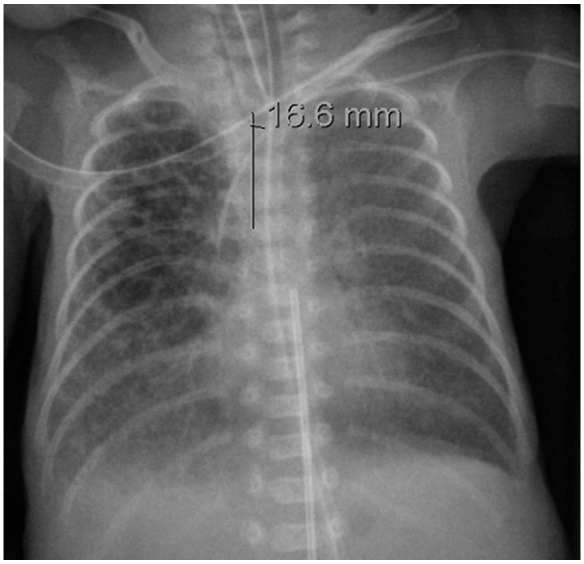

Figure 37–5. Pulmonary interstitial emphysema. Anteroposterior chest radiograph shows multiple rounded lucencies in the right upper lobe secondary to interstitial emphysema.

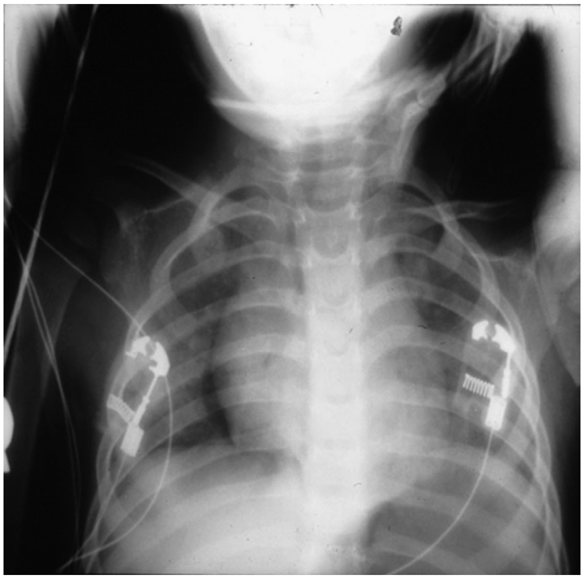

Figure 37–6. Pneumomediastinum. Anterioposterior chest radiograph shows lateral displacement of the mediastinal pleura.

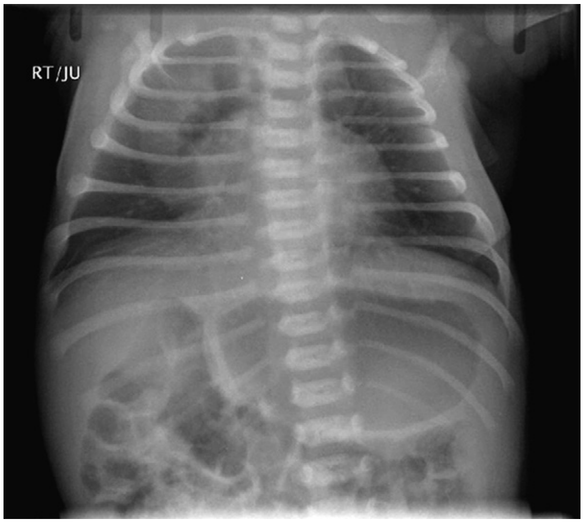

Figure 37–7. Pneumomediastinum. Anteroposterior chest radiograph shows superior elevation of the thymus (thymic sail sign).

NEONATAL PNEUMONIA

Most neonatal pneumonias are of bacterial origin, including streptococci, *Staphylococcus aureus*, and *Escherichia coli*. These infections may be acquired in utero, during delivery, or

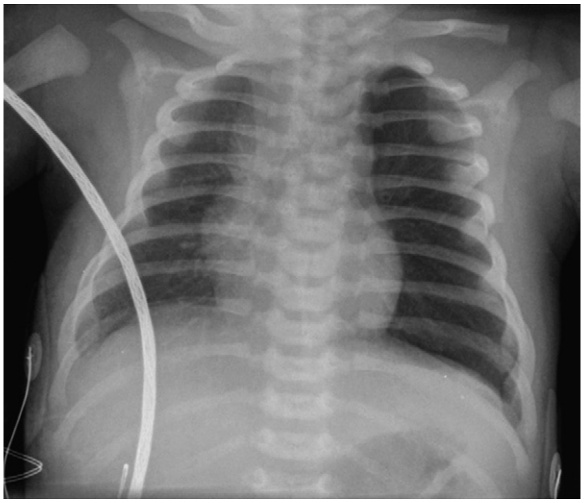

Figure 37–8. Pneumothorax. Anteroposterior chest radiograph shows increased left thoracic lucency.

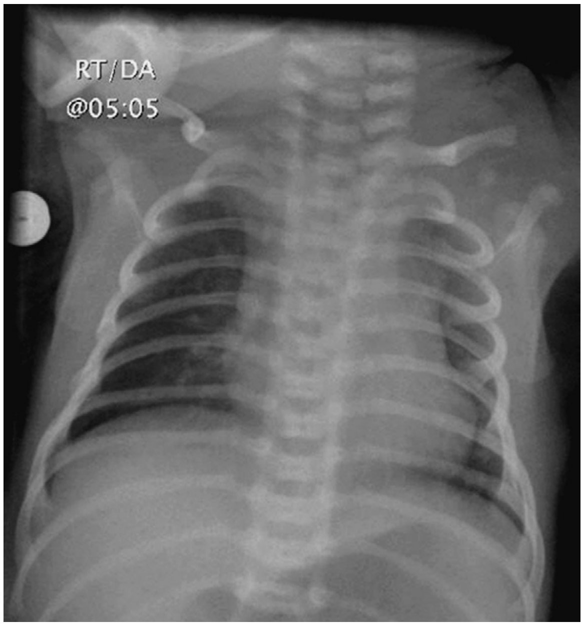

Figure 37–9. Pneumothorax. Anteroposterior chest radiograph shows a deep right costophrenic sulcus.

after birth. The radiographic appearance of neonatal bacterial pneumonia is typically identical to that of RDS and is characterized by diffuse ground-glass opacities of variable severity.[1,21] Focal, lobar disease is unusual in neonatal bacterial pneumonias, as the interlobar fissures are incompletely formed and the infection typically disseminates widely throughout the lungs. Peripheral air bronchograms may be noted with increased severity of disease. Pleural effusions may be present. The presence of pleural fluid should raise the suspicion of infection, as effusions are uncommon in RDS. Viral pneumonia can also be seen in the newborn period. These demonstrate less specific findings at chest radiography: the radiograph may be normal or demonstrate streaky, perihilar linear markings. The peripheral lung parenchyma is usually clear.

TRANSIENT TACHYPNEA OF THE NEWBORN

Transient tachypnea of the newborn is also referred to as wet lung disease or retained fluid syndrome. It may be associated with delivery by cesarean section, and it is felt to result from excessive retention of lung fluid after delivery. This is typically a clinical diagnosis, as the radiographic appearance is varied and nonspecific. The radiographic findings may be normal. Radiographic abnormalities include streaky, perihilar opacities and lung overinflation. Occasionally, small pleural effusions may be seen. The radiographic changes are usually symmetric, although occasionally some asymmetry may be noted. The radiographic and clinical findings usually resolve within the first 24 to 48 hours of life. Ultrasonography has recently been proposed as a technique to diagnose transient tachypnea of the newborn and the accompanying lung fluid.[13]

MECONIUM ASPIRATION SYNDROME

The expulsion of meconium before birth is often related to fetal distress leading to a hypoxia-induced vagal response. It occurs more commonly in full-term or postmature infants. The aspirated meconium causes obstruction of small airways. The typical radiographic appearance of meconium aspiration includes coarse, nodular opacities, which probably represent the inspissated meconium in small airways and associated atelectasis (Fig. 37-10).[23] The distribution of disease is often asymmetric. In addition, there is usually lobar or segmental lung overinflation. The radiographic changes may be present immediately after birth or develop over the first few hours of life. Complications include pneumothorax and pneumomediastinum.

PULMONARY HEMORRHAGE

Pulmonary hemorrhage in infants may result from hypoxia-induced capillary damage and may be a manifestation of pulmonary edema. More significantly, patent ductus

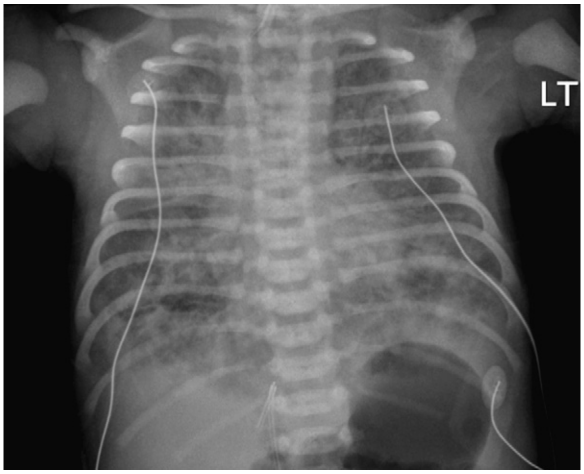

Figure 37–10. Meconium aspiration. Anteroposterior chest radiograph demonstrates coarse nodular opacities throughout both lung fields.

arteriosus with left-to-right shunting is well accepted as an etiology of pulmonary hemorrhage. In intubated patients, the diagnosis is usually established by detecting blood in the endotracheal tube. The appearance of pulmonary hemorrhage at chest radiography is variable and nonspecific. Small amounts of hemorrhage may not be detected at chest radiography, but more extensive hemorrhage results in focal or diffuse ground-glass opacities. The latter appearance can mimic pneumonia or pulmonary edema. The radiographic changes from uncomplicated pulmonary hemorrhage are usually transient, resolving within 24 to 48 hours.

BRONCHOPULMONARY DYSPLASIA

Chronic lung disease in the premature infant treated with high oxygen concentrations and mechanical ventilation is labeled bronchopulmonary dysplasia.[26] It may occur after RDS, but may also be seen in association with neonatal pneumonia, meconium aspiration, and congenital cardiac disorders. The condition results from multiple factors, including lung immaturity, exposure to chronic low-grade chorioamnionitis, high oxygen concentrations, volutrauma, and barotrauma. The incidence of bronchopulmonary dysplasia is increased in infants who develop pulmonary interstitial emphysema and pneumothorax.[41] The radiographic findings vary over time. Initially, the appearance is similar to that of RDS and is characterized by diffuse ground-glass opacities of variable severity (Fig. 37-11).[3] Gradually, the radiographic appearance changes and is characterized by the development of coarse opacities that are often patchy or asymmetric in their distribution (Fig. 37-12).[3,20,42] Frequently, focal areas of air trapping are also noted. In severe cases, cystic areas are noted throughout the lung parenchyma; these represent emphysema.

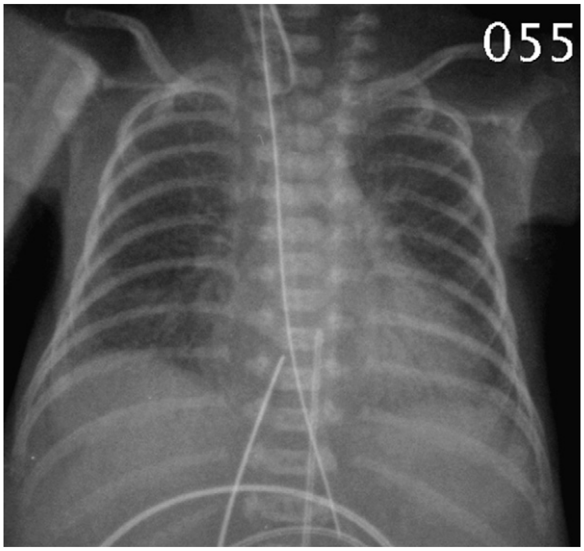

Figure 37–11. Bronchopulmonary dysplasia. Anteroposterior chest radiograph in a 4-week-old infant demonstrates diffuse ground-glass opacities of moderate severity.

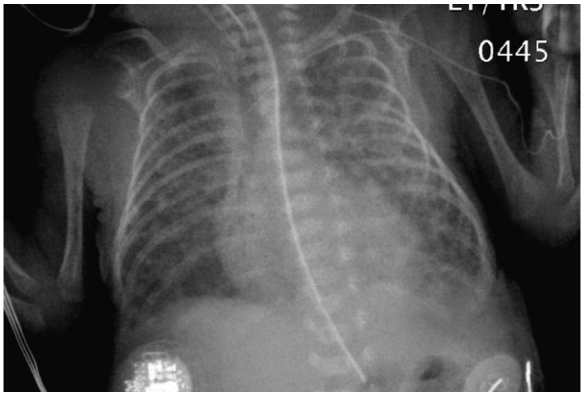

Figure 37–12. Bronchopulmonary dysplasia. Anteroposterior chest radiograph in same infant as shown in Figure 37-11, 2 months later, shows diffuse, coarse parenchymal opacities.

In recent years, the widespread adoption of antenatal glucocorticoid administration and postnatal surfactant therapy has resulted in a decreased need for high oxygen exposure and ventilatory pressure. In conjunction with the increased survival of very-low-birthweight infants, this has resulted in a more insidious development of bronchopulmonary dysplasia in the absence of prior severe RDS or barotrauma. Initially, infants with this condition may have little or no radiographic evidence of lung disease, but subsequently they require supplemental oxygen or mechanical ventilation over the first several weeks of life and manifest typical radiographic findings associated with chronic lung disease.

Respiratory Disease: Surgically Treated Causes

CONGENITAL DIAPHRAGMATIC HERNIA

Congenital diaphragmatic hernia typically develops posteriorly and laterally through patent pleuroperitoneal canals, also known as the foramina of Bochdalek. It results from defective fusion of the pleuroperitoneal membranes during embryologic development. Bowel and solid organs may herniate into the affected hemithorax. Congenital diaphragmatic hernia occurs more commonly on the left side. The characteristic radiographic appearance is of air-filled bowel loops in the thorax (Fig. 37-13) and a paucity of bowel loops in the abdomen. The major alternative diagnostic consideration is cystic adenomatoid malformation, as parenchymal cysts may at times be difficult to differentiate from bowel loops. Initially, the bowel loops may be fluid filled, making the diagnosis difficult (Fig. 37-14). The ipsilateral lung is almost universally hypoplastic because the mass effect in utero affects development. There is often hypoplasia of the contralateral lung. Pulmonary hypertension is often present in these infants at birth.

CYSTIC ADENOMATOID MALFORMATION

Cystic adenomatoid malformation results from anomalous development of terminal respiratory structures, resulting in replacement of normal lung by adenomatoid proliferation of bronchial structures, which form cysts and lack alveoli. The

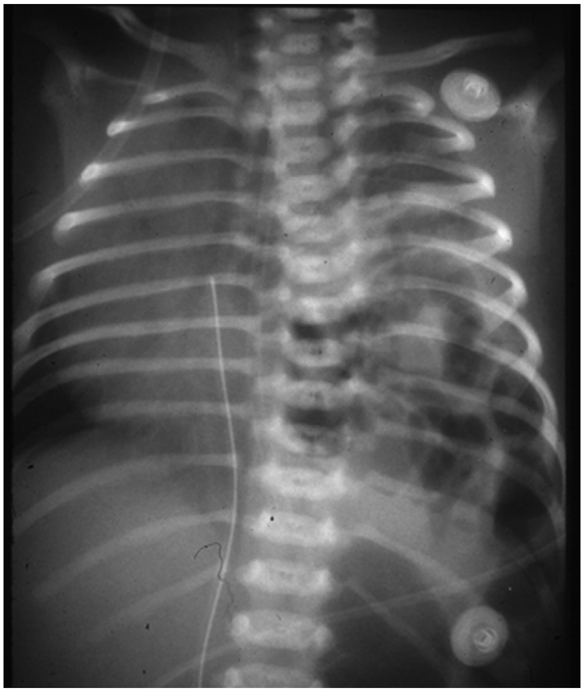

Figure 37–13. Congenital diaphragmatic hernia. Anteroposterior chest radiograph shows multiple bowel loops in the left hemithorax. Note the mediastinal shift from left to right.

impetus for hamartomatous change is unclear. One lobe is involved in two thirds of cases, and two lobes are involved in one third. Three types of lesions are described radiographically. The type I lesion is characterized by one or more large cysts (>2 cm). This is the most common type. The type II lesion contains multiple small cysts that are rarely over 1 cm in diameter. The type III lesion appears solid due to the presence of multiple microcysts (<0.5 cm). As a result, there is a spectrum in the radiographic appearance of these lesions ranging from multiple microcysts to a dominant cyst or solid mass (Fig. 37-15).[43] Focal emphysematous changes are often seen surrounding the lesion. CT is useful in the assessment of smaller lesions that may not be well seen by chest radiography (Fig. 37-16). There is an association of cystic adenomatoid malformation and extralobar pulmonary sequestration.

CONGENITAL LOBAR OVERINFLATION (CONGENITAL LOBAR EMPHYSEMA)

Congenital lobar overinflation or emphysema (see Chapter 44) results from a focal bronchial ball-valve obstruction that results in overdistention of the distal airways within a pulmonary lobe or segment. The condition typically involves one or two lobes. There is a lobar predilection: the left upper lobe is involved most frequently, followed by the right middle lobe and the right upper lobe. Radiographically, it is characterized by a focal area of hyperlucency and increased volume (Fig. 37-17).[43] There may be compression of adjacent lung. There is usually progressive hyperinflation of the involved lobe over time. Initially after birth, there may be increased opacity within the involved lobe as a result of retained fluid. CT is useful in the precise characterization of involved lobes and the degree of adjacent lung compression.

ESOPHAGEAL ATRESIA AND TRACHEOESOPHAGEAL FISTULA

The pairing of the terms esophageal atresia and tracheoesophageal fistula describes a disorder in formation and separation of the primitive foregut and esophagus. A spectrum of malformations is noted, ranging from esophageal atresia (with or without a proximal or distal tracheoesophageal fistula) to a tracheoesophageal fistula without esophageal atresia. The most common type, involving proximal esophageal atresia with a distal tracheoesophageal fistula, accounts for more than 80% of cases.

At chest radiography, a blind-ending, air-filled proximal esophageal pouch is noted with the most common type (Fig. 37-18).[5] The presence of a distal fistula is supported by air in the gastrointestinal tract. Occasionally, an esophagram is performed to confirm a tracheoesophageal fistula. When an esophagram is performed in an infant with a blind-ending proximal esophageal pouch, an enteric tube is carefully placed into the proximal segment and the infant is examined in the lateral plane. A small amount of contrast (usually only 2 to 3 mL is required) is slowly injected

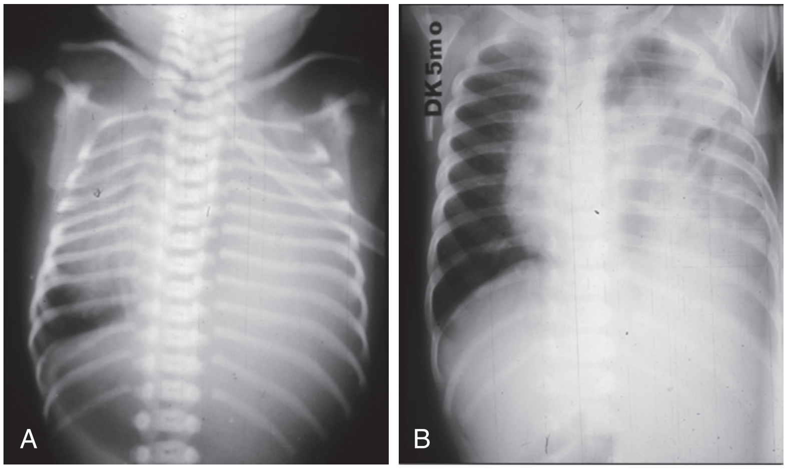

Figure 37–14. Congenital diaphragmatic hernia. **A**, Initial anteroposterior chest radiograph shows an opacified left hemithorax. **B**, Anteroposterior chest radiograph 24 hours later shows air-filled bowel loops in the left hemithorax.

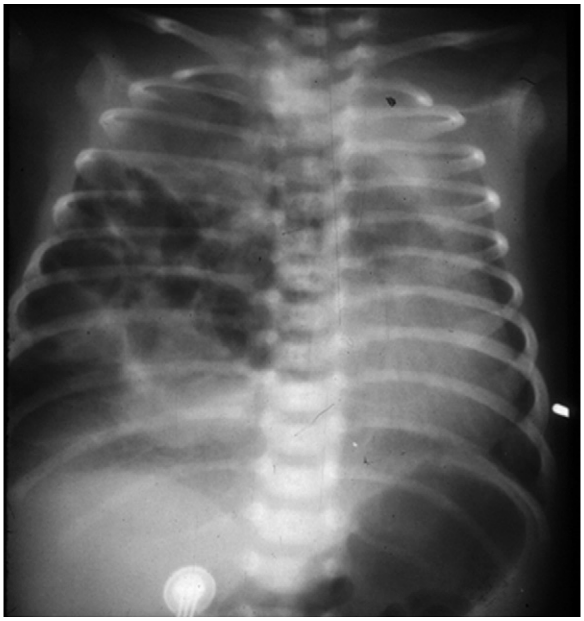

Figure 37–15. Cystic adenomatoid malformation. Anteroposterior chest radiograph demonstrates a multicystic mass in the right lung, resulting in mediastinal shift and compression of left lung.

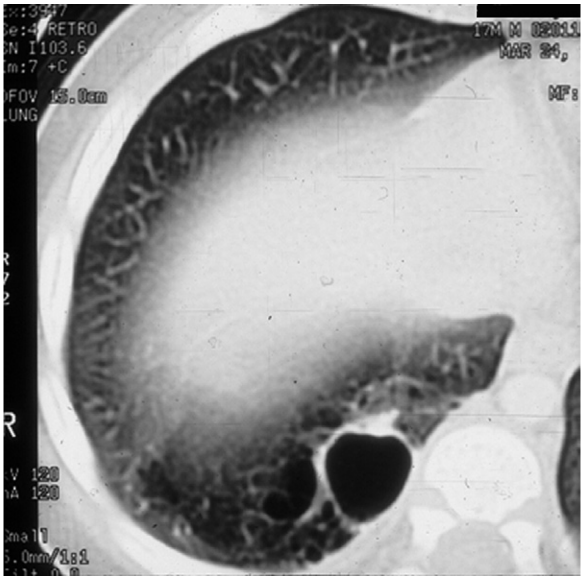

Figure 37–16. Cystic adenomatoid malformation. Chest CT demonstrates a parenchymal cyst in the right lower thorax with surrounding focal emphysematous change.

(Fig. 37-19). After confirmation that no proximal fistula is present, the administered contrast material should be withdrawn.

Tracheoesophageal fistula is associated with multisystem abnormalities in approximately one third of cases, including vertebral, cardiac, renal, limb, and other gastrointestinal tract atresias. All infants with a tracheoesophageal atresia should undergo a renal ultrasound to evaluate possible associated renal anomalies.

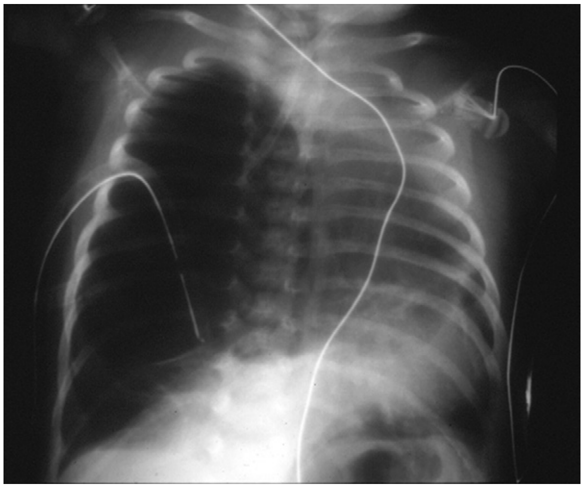

Figure 37–17. Congenital lobar overinflation. Anteroposterior chest radiograph shows marked overinflation of the right upper and middle lobes, resulting in displacement of mediastinal structures to the left and compression of normal left lung.

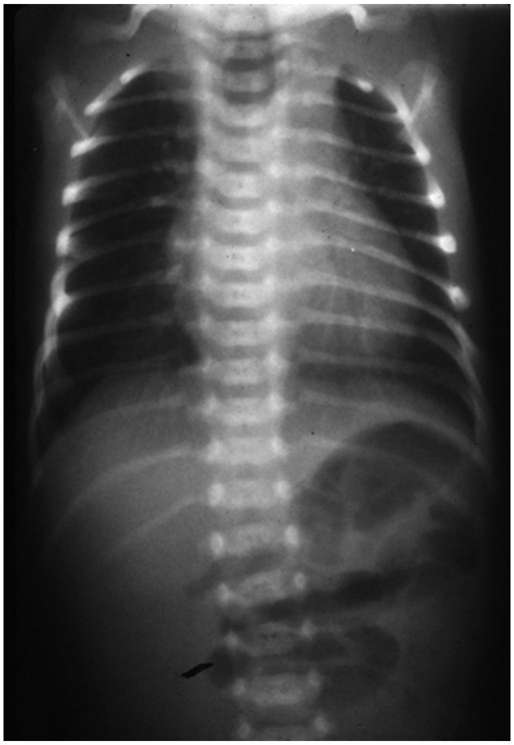

Figure 37–18. Tracheoesophageal fistula. Anteroposterior chest radiograph demonstrates an air-filled blind-ending esophageal pouch in the neck.

HEART

Cardiac problems in infants are usually congenital in origin. Although radiography is an important part of the evaluation of children with suspected cardiac disease, it alone rarely leads to a specific diagnosis. Rather, its usefulness here is in

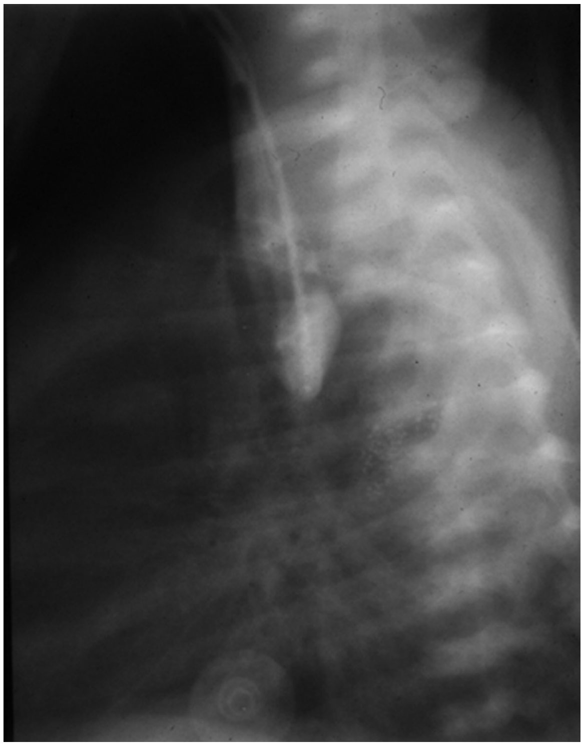

Figure 37–19. Tracheoesophageal fistula. Lateral spot radiograph following contrast injection shows a blind-ending proximal esophageal pouch.

the exclusion of pulmonary conditions as a cause of the respiratory distress. The clinical examination and cardiac echocardiography are the primary means of diagnosing congenital heart conditions.

Great variability in cardiac size is found in congenital heart anomalies. Typically, cardiomegaly is present in infants and neonates with large left-to-right shunts (ventricular septal defect, atrioventricular canal), Ebstein anomaly, or hypoplastic left heart syndrome, or in association with cardiomyopathy. In addition, cardiomegaly may be seen transiently in the absence of cardiac disease in association with hypoglycemia, hypocalcemia, or severe anemia, as well as in infants of diabetic mothers. Enlargement of specific cardiac chambers cannot be assessed by chest radiography in infants and young children.

In cyanotic congenital heart disease, the caliber of the pulmonary arteries is reduced, the hila appear small, and the lungs may appear more lucent. However, the distinction between normal and decreased pulmonary arterial vascularity cannot be made accurately by chest radiography. It is difficult to differentiate normal from small pulmonary vessels, as there is too much overlap in their appearance. Persistent pulmonary hypertension may mimic cyanotic congenital heart disease, both clinically and radiographically, because of cardiomegaly and pulmonary oligemia.

Radiography is useful in diagnosing increased pulmonary arterial vascularity associated with large left-to-right shunts, including patent ductus arteriosus, ventricular septal defect, atrial septal defect, and endocardial cushion defect. Increased pulmonary arterial vascularity is seen at radiography when the ratio of left-to-right shunt is greater than 3:1. Increased branching linear shadows will be seen in the perihilar region, and vascular markings will be seen in the periphery of the lung fields. The pulmonary arterial vascularity usually appears normal with shunts of a lesser degree.

GASTROINTESTINAL TRACT

Intestinal obstruction is the most common abdominal emergency in the newborn period. Neonatal obstruction is typically characterized as high (occurring proximal to the distal ileum) or low (involving the distal ileum or colon).[9] The clinical presentations of infants with high and those with low intestinal obstruction may overlap and include abdominal distention, vomiting, and poor feeding. The vomitus is often bilious. Low obstructions are often characterized by failure to pass meconium.

Abdominal radiographs are the initial imaging examination of choice to distinguish between high and low intestinal obstruction. Radiographs in infants with high intestinal obstruction typically show few dilated bowel loops (Fig. 37-20), whereas radiographs in infants with low obstruction show many dilated bowel loops (Fig. 37-21). When bowel obstruction is present, the bowel loops often become elongated and are stacked in a parallel fashion in addition to showing dilation. The distinction between high and low intestinal obstruction is important, as infants with a high obstruction may not need further imaging evaluation.[9,39] If they do require further imaging assessment, the upper gastrointestinal series is the examination of choice.

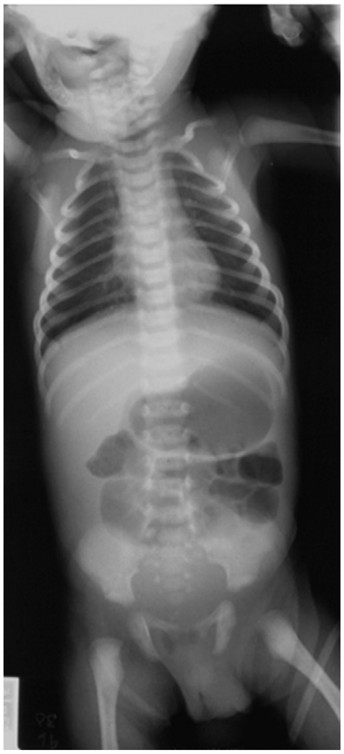

Figure 37–20. High intestinal obstruction. Supine abdominal radiograph in an infant with midgut malrotation demonstrates dilated proximal small bowel loops and absence of distal bowel gas.

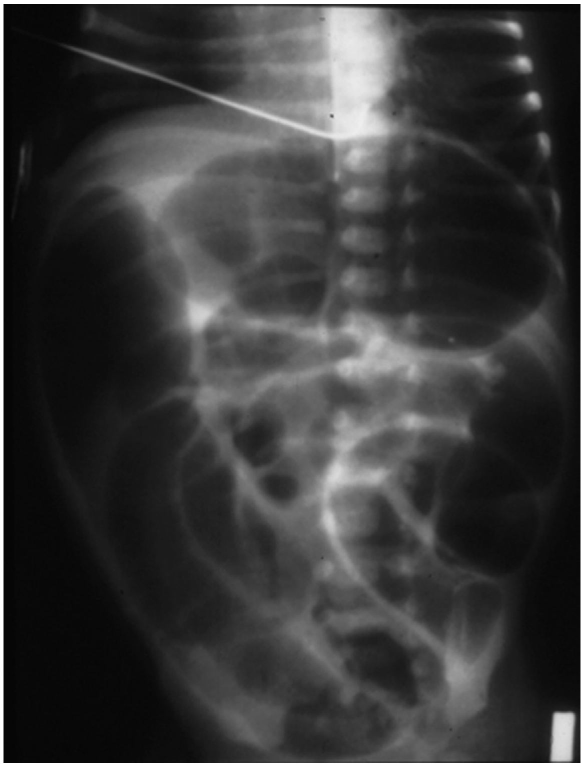

Figure 37–21. Low intestinal obstruction. Supine abdominal radiograph in an infant with Hirschsprung disease demonstrates multiple dilated bowel loops.

Infants with a suspected low obstruction are typically evaluated with a contrast enema.[9,39]

As was discussed under "Chest," earlier, proper patient positioning is important, as rotation distorts the image and makes evaluation of abdominal pathology difficult. Portable abdominal radiographs are obtained in the AP view with the infant lying supine. With proper positioning, the radiograph should demonstrate symmetry of the lower ribs and a midline appearance of the lumbar vertebrae. Extraneous objects including electrodes and leads should be removed from the field of view whenever possible, as they can obscure abnormalities on the radiograph.

High Intestinal Obstruction

MIDGUT MALROTATION

Midgut malrotation is the most important cause of upper intestinal obstruction. Abnormal in utero rotation of the midgut results in abnormal mesenteric fixation. The lack of normal fixation of the mesentery results in a short mesenteric base that may lead to bowel twisting around the axis of the superior mesenteric artery, with resulting vascular compromise, bowel ischemia, and necrosis. Most infants with malrotation present with bilious vomiting. Nearly 40% of patients present in the first week of life.[4] Bilious vomiting in an infant should be considered a potential surgical emergency, and in the absence of another defined cause, midgut malrotation should be excluded from the diagnosis if possible.

The findings at abdominal radiography associated with midgut malrotation are variable and include duodenal obstruction (secondary to Ladd bands, which are normal peritoneal attachments) or a mid–small bowel obstruction from a midgut volvulus.[4,9] The abdominal radiographic findings may also be normal in infants with malrotation, so normal results on an abdominal radiograph do not exclude the condition. The diagnostic examination of choice is the upper gastrointestinal (UGI) examination, which shows an abnormal duodenal-jejunal junction (Fig. 37-22). The normal duodenal-jejunal junction should be located to the left of the spine and at the same level as, or more superior to, the duodenal bulb.[9,36] Therefore, if the duodenal-jejunal junction is lower than the duodenal bulb or does not cross to the left of the vertebral pedicle, the diagnosis is midgut malrotation. If a midgut volvulus is present, a spiral or corkscrew appearance of the duodenum and jejunum is noted.

Cross-sectional imaging with sonography or CT can also diagnose midgut malrotation by demonstrating inversion of the mesenteric vessels. The superior mesenteric vein is normally to the right of the superior mesenteric artery. If the vein is to the left of the artery, that is typically diagnostic of midgut malrotation, although the diagnosis should be confirmed with an UGI examination. Cross-sectional imaging is not sensitive or specific enough to be the gold standard for this diagnosis.

DUODENAL ATRESIA

Duodenal atresia is the most common cause of high intestinal obstruction in the newborn. It occurs more commonly than duodenal stenosis or web. Approximately 75% of cases occur proximal to the papilla of Vater and are associated with bilious vomiting. There is an association with Down syndrome

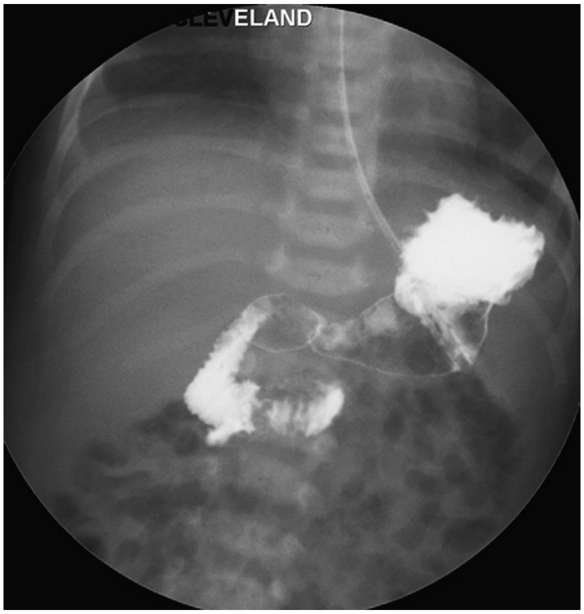

Figure 37–22. Midgut malrotation. Spot film from an upper gastrointestinal series shows an abnormal location of the duodenal-jejunal junction. It is located below the level of the duodenal bulb.

and congenital heart disease. Abdominal radiography typically shows gastric distention and a dilated duodenal bulb referred to as the *double bubble* (Fig. 37-23). These findings are diagnostic for duodenal atresia, and when they are present, no further study is necessary.

JEJUNAL ATRESIA

Jejunal atresia results from an ischemic injury to the developing small intestine. The injury may result from a vascular accident or a mechanical obstruction, such as an in utero volvulus. A single focal area of atresia may be noted, or there may be multiple atretic segments. Abdominal radiographs typically demonstrate dilated small bowel loops that may contain air-fluid levels indicative of a mid–small bowel obstruction.

Low Intestinal Obstruction

HIRSCHSPRUNG DISEASE

Hirschsprung disease is characterized by the absence of myenteric plexus ganglion cells, which results in a failure of normal colonic relaxation and subsequent obstruction. Most infants present in the first 6 weeks of life with abdominal distention, constipation, vomiting, and occasionally diarrhea. The condition is more common in male than in female infants. Abdominal radiographic findings in Hirschsprung disease are usually nonspecific. They typically demonstrate variable dilation of small and large bowel. There is often absence of air in the rectum. Tubular filling defects that may be noted in the colon represent meconium or stool. The diagnostic examination of choice is a contrast enema. The contrast material of choice is either barium sulfate or water-soluble contrast. Water-soluble contrast is preferred, as it can help promote the passage of meconium. A small, soft catheter should be used. If a balloon catheter is used, the balloon should not be inflated, as it may obscure any pathologic findings. The examination should start with the patient in the lateral position to better allow for demonstration of the transition zone between normal, dilated colon and contracted, aganglionic distal colon and rectum (Fig. 37-24). The transition zone is located most frequently in the rectosigmoid region. The affected segment always includes rectum and a variable length of more proximal colon. There are never any skip areas. Contrast enema is diagnostic in the majority of patients. However, the examination results may be normal early on if the normal segment of colon has not yet become dilated because of stool impaction. In addition, the transition point identified at contrast enema does not always correlate with the pathologic extent of aganglionic colon.[25] Approximately 5% of patients have total colonic aganglionosis and demonstrate a microcolon without a transition zone.[6,39]

FUNCTIONAL IMMATURITY OF THE COLON

Functional immaturity of the colon is also known as meconium plug syndrome or small left-colon syndrome. It is thought to be associated with immaturity of the myenteric plexus ganglia. There is an association with maternal diabetes mellitus, eclampsia, and prematurity. Abdominal radiography shows a distal bowel obstruction with or without air-fluid

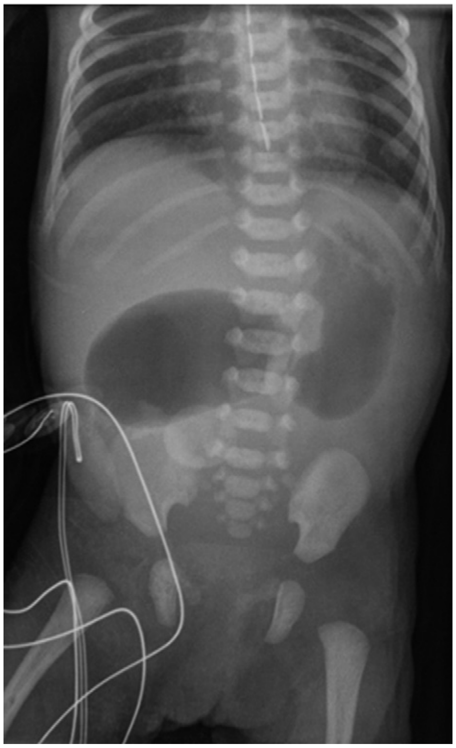

Figure 37–23. Duodenal atresia. Supine abdominal radiograph demonstrates a “double bubble,” representing dilated stomach and duodenum.

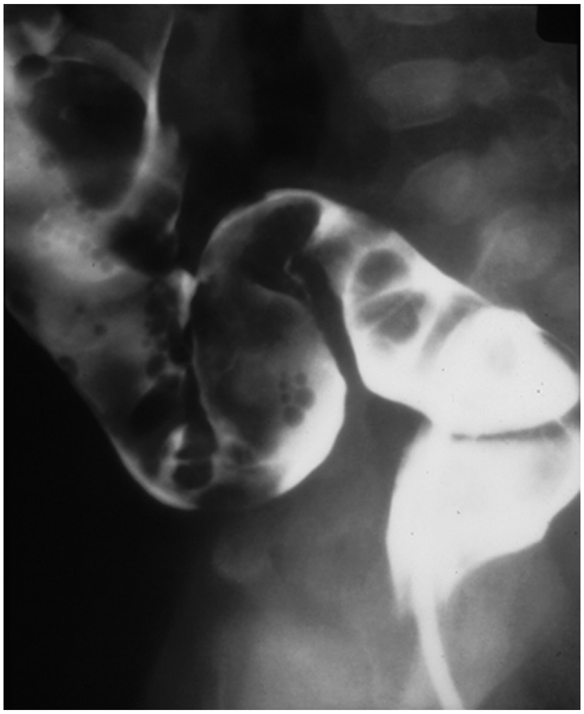

Figure 37–24. Hirschsprung disease. Lateral view from a contrast enema demonstrates a transition zone. The more proximal colon is dilated, whereas the caliber of the distal, aganglionic segment is normal.

levels. Contrast enema shows multiple filling defects representing meconium plugs. The caliber of the colon is variable: it may be normal in its entirety or there may be a small-caliber left colon to the level of the splenic flexure with dilated proximal colon (Fig. 37-25). The contrast enema is often therapeutic in these patients, helping to evacuate residual meconium.

MECONIUM ILEUS

Meconium ileus is caused by abnormal meconium inspissation in the distal ileum. It is usually associated with cystic fibrosis.[15] The abnormal meconium produced in these infants results in a distal small bowel obstruction. Abdominal radiography demonstrates multiple dilated small bowel loops indicative of a low obstruction. A soap bubble appearance may be noted in the right side of the abdomen. Meconium ileus may be complicated by in utero perforation, resulting in meconium peritonitis. This in turn results in calcification of intraperitoneal meconium. Contrast enema should be performed in these infants. It typically demonstrates a microcolon consisting of a diffusely small-caliber colon (Fig. 37-26).[6] The contrast enema may have a therapeutic effect in some infants with meconium ileus, particularly if reflux can be achieved into the distal ileum, where much of the inspissated meconium is located.[27]

ILEAL ATRESIA

The underlying mechanism in ileal atresia is a vascular accident similar to jejunal atresia, or it may result from meconium ileus. When one area of bowel atresia is present, the incidence of multiple atresias is increased. Abdominal radiographs in neonates with ileal atresia usually show a low intestinal obstruction pattern. Contrast enema demonstrates a microcolon.[6]

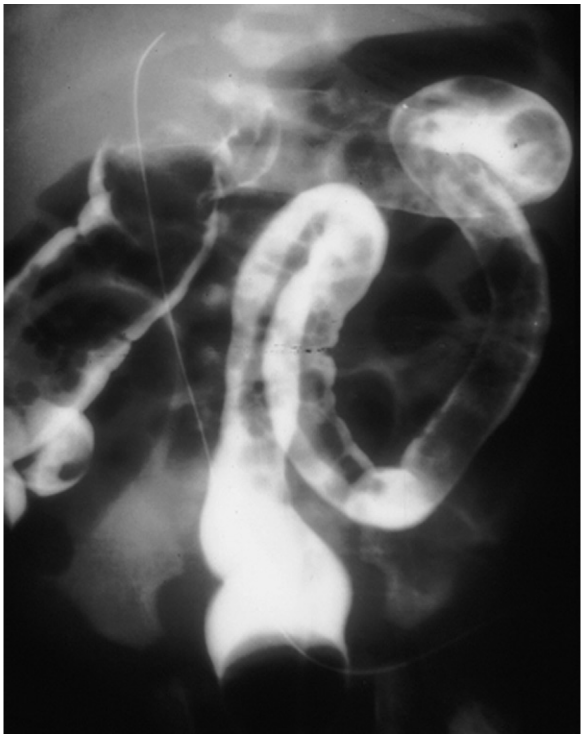

Figure 37–25. Small left colon syndrome. Contrast enema demonstrates a small-caliber descending colon. Note the caliber difference between transverse and descending colon.

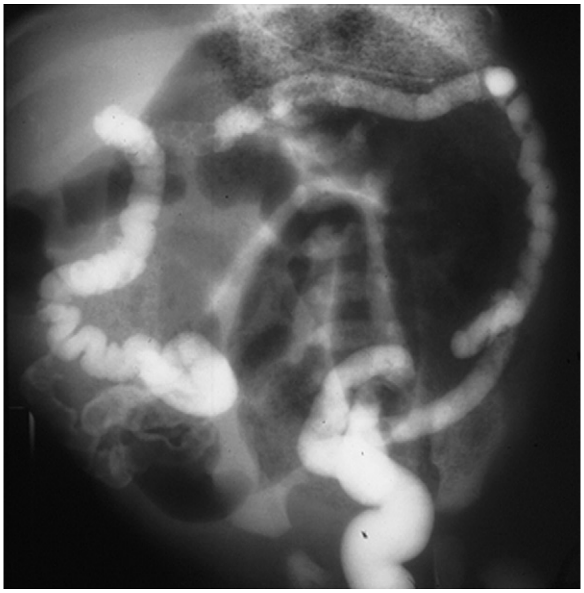

Figure 37–26. Meconium ileus with microcolon. Contrast enema in an infant with meconium ileus demonstrates a microcolon.

ANORECTAL MALFORMATION

These complex sets of anomalies result from improper descent of the hindgut. The level of obstruction is characterized as high or low if the obstruction is above or below the puborectalis muscle. Pelvic radiographs and sonography have been utilized to determine the distance between distal bowel and anal dimple; however, neither of these methods can precisely measure that distance. MRI is useful for surgical planning by allowing localization of distal bowel to the puborectalis muscle. High obstructions typically have a fistula to the bladder. This can be demonstrated through a voiding cystourethrogram. Low obstructions typically have a fistula to the lower urethra, vagina, or perineum.

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) is seen predominantly in premature infants. It is the most common acquired gastrointestinal emergency in the neonatal intensive care unit. It appears to result from a combination of mesenteric ischemia from splanchnic vasoconstriction, thrombosis, or low perfusion states, infection and exposure to feeds, especially formula. The most commonly involved location is the ileocecal region. Infants usually present with abdominal distention, abdominal tenderness, feeding disturbance, and guaiac-positive stools.

Abdominal radiography plays an important role in the diagnosis of NEC. In normal neonates, gas is most often present through most of the small and large bowels, and each gas-filled loop causes an impression on adjacent loops. These loops develop a multifaceted configuration resembling a "mosaic." Early radiographic findings of NEC are nonspecific and include bowel dilation and bowel wall thickening.[18,30] Focal or asymmetric distribution of bowel dilation is a more worrisome finding. It is even more worrisome if the asymmetric pattern persists and the dilated bowel loops maintain the same appearance as fixed loops on follow-up radiographs. This suggests the appearance of full-thickness necrosis and may precede clinical deterioration. As the disease progresses further, intramural air or pneumatosis intestinalis is seen.[14,18,30,31] Pneumatosis intestinalis is considered to be specific for the diagnosis, but the findings may be transient, lasting only minutes or hours.[14] At radiography, pneumatosis appears as a "bubbly" pattern or a curvilinear pattern (Fig. 37-27). The bubbly pattern is difficult to differentiate from stool, but the presence of formed stool that would resemble pneumatosis is uncommon in sick premature infants. Pneumatosis is most commonly seen in the right lower quadrant. Air is also occasionally seen in the porta hepatis, where it appears as branching, linear lucencies overlying the liver (Fig. 37-28).[31] They extend from the region of the main portal vein toward the periphery of both hepatic lobes. In NEC, portal venous air is an extension of intramural air that passes into the portal venous system. Portal venous air is typically a late finding seen in more severely affected cases.

Sonography has also been utilized in the evaluation of NEC.[50] Sonography can depict pneumatosis intestinalis as hyperechoic foci in the bowel wall. In contrast to intraluminal gas, intramural gas will not change in position because of peristalsis or changes in patient position. Sonography can also depict portal venous air as intraluminal echogenic foci within the liver (Fig. 37-29). Finally, sonography has been used in the detection of abdominal fluid collections that may be seen following perforation and abscess formation. The presence of focal peritoneal fluid collections or free peritoneal fluid containing internal echoes correlates with bowel perforation and abscess formation or peritonitis.

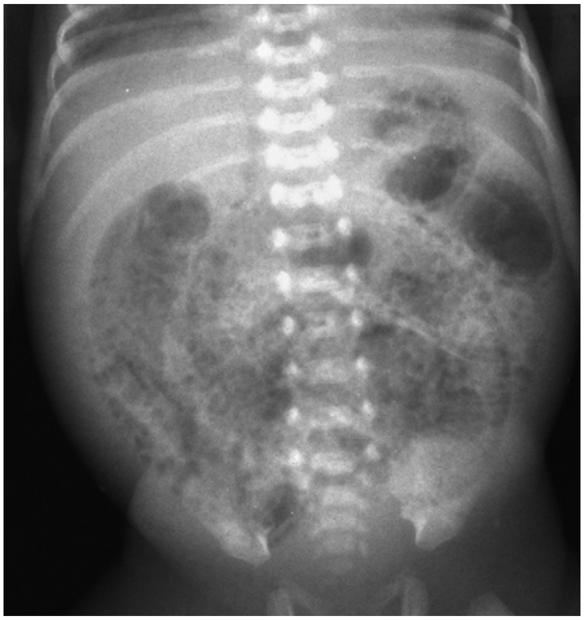

Figure 37–27. Necrotizing enterocolitis (NEC) with pneumatosis intestinalis. Supine abdominal radiograph in an infant with NEC demonstrates diffuse pneumatosis intestinalis.

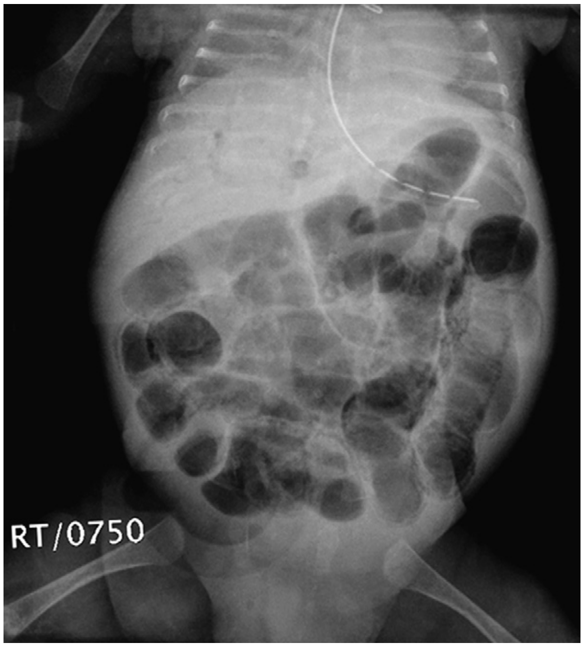

Figure 37–28. Necrotizing enterocolitis (NEC) with portal venous air. Supine abdominal radiograph in an infant with NEC demonstrates linear lucencies overlying the liver and representing portal air. Also note diffuse pneumatosis intestinalis.

Once the diagnosis of NEC is established, serial imaging is usually performed to evaluate for possible bowel perforation. Most bowel perforations occur in the first 48 hours after the initial diagnosis.[40] Abdominal radiography is the standard method for detecting pneumoperitoneum. A cross-table lateral radiograph or right-side-up decubitus radiograph of the

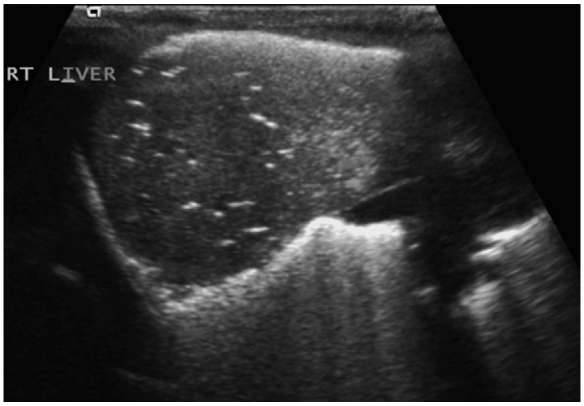

Figure 37–29. Portal venous air. Sonogram of the liver demonstrates multiple echogenic foci within the liver, representing portal venous air.

abdomen is useful for assessing peritoneal air. Following perforation, peritoneal air collects in the most superior portion of the abdomen. Peritoneal air appears as triangular lucencies between bowel loops anteriorly just beneath the abdominal wall (Fig. 37-30) or as small collections of gas anterior or lateral to the liver. On the supine view, large amounts of peritoneal air give rise to the "football" sign, where air outlines the superior abdomen with the falciform ligament creating the appearance of the lacing of the football (Fig. 37-31).

A delayed complication of NEC is bowel stricture. It represents the sequela of necrotic lesions from the bowel wall to the inner muscularis. Strictures occur in 20% to 30% of survivors of NEC. Strictures may be single or multiple and are usually located in the colon. The most common site is the splenic flexure. A contrast enema is useful for identifying a possible stricture. Water-soluble contrast should be utilized. A focal area of narrowing can be noted (Fig. 37-32).

HEPATOBILIARY TRACT

Sonography is the imaging examination of choice for the initial evaluation of suspected congenital or acquired hepatobiliary abnormalities in infants. Cross-sectional imaging with CT and MRI is utilized selectively in the characterization of hepatic masses.

Biliary Atresia

The underlying abnormality in biliary atresia is obliteration of the extrahepatic biliary tree and variable obliteration of portions of the intrahepatic biliary tree. Infants present with jaundice early. The clinical challenge is to differentiate biliary atresia from neonatal hepatitis. There is overlap between the

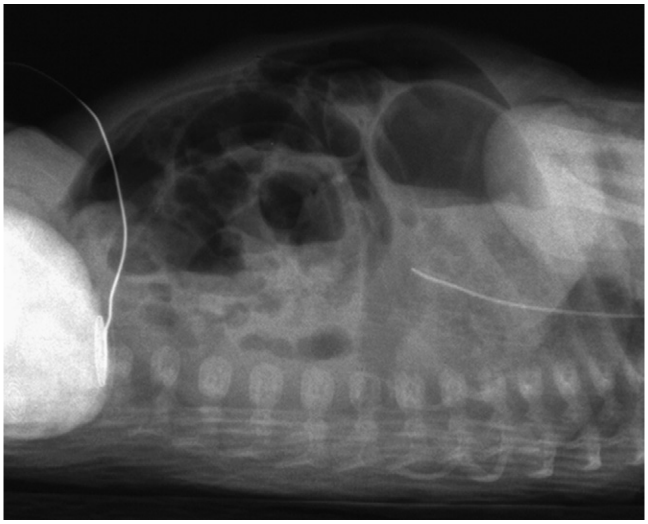

Figure 37–30. Pneumoperitoneum. Cross-table lateral view of the abdomen demonstrates an anterior extraluminal air collection.

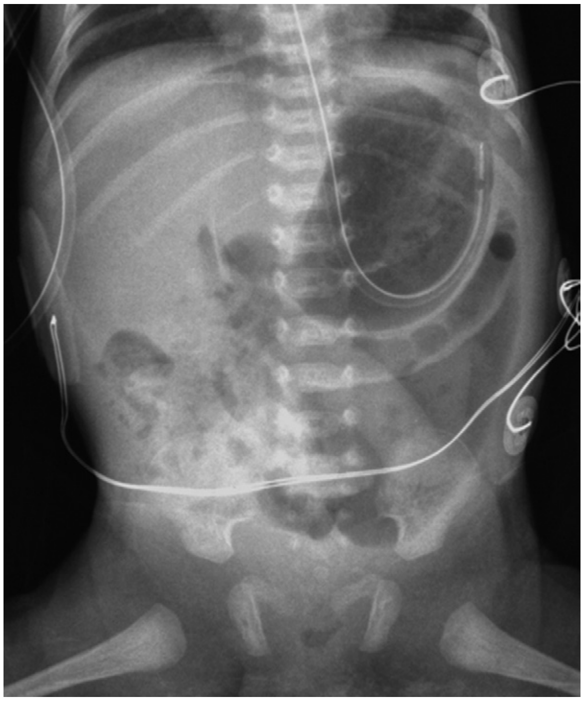

Figure 37–31. Pneumoperitoneum. Anteroposterior view of the abdomen shows a large rounded collection of extraluminal air in the upper abdomen (football sign).

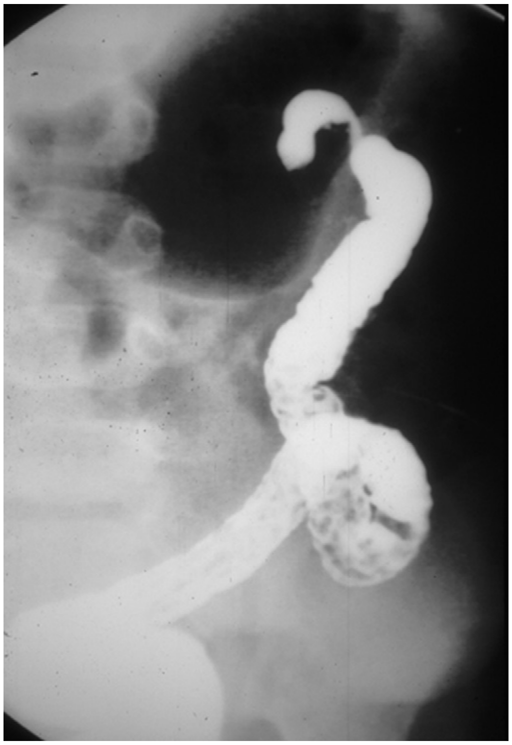

Figure 37–32. Colonic stricture after necrotizing enterocolitis (NEC). Image from a contrast enema examination in a 7-week-old infant demonstrates focal narrowing at the splenic flexure, representing a focal stricture. The infant had been treated for NEC 4 weeks before this examination.

two conditions, and they may represent a spectrum of severity rather than distinct entities.[32] They both result in conjugated hyperbilirubinemia. The principal difference between the two entities is that there is patency of the biliary tree in infants with neonatal hepatitis.

Sonography is usually the initial imaging examination in children with neonatal jaundice. Sonography is used to exclude other causes of jaundice, including choledochal cyst, biliary sludge, and cholelithiasis. However, in most cases of biliary atresia, the sonographic findings are nonspecific. The most specific sonographic finding is the triangular cord sign.[28,45] This echogenic linear band in the porta hepatis anterior to the portal vein represents the fibrous tissue in the porta hepatis. The gallbladder is not identified in approximately 80% of patients and is usually small in the remainder.[28,34,45] Hepatic parenchymal echogenicity may also be abnormal.

The hepatobiliary scan with iminodiacetic acid compounds is used for diagnosis of biliary atresia. The infant is pretreated with phenobarbital. The diagnosis is made if gastrointestinal excretion of the administered isotope is absent after 24 hours.[38] Biliary atresia is associated with a variety of other abnormalities, including choledochal cyst, polysplenia, preduodenal portal vein, and azygous continuation of the inferior vena cava.[2]

Choledochal Cyst

A choledochal cyst represents cystic dilation of the extrahepatic or intrahepatic biliary tree. Among the proposed underlying etiologies are weakness of the lining of the biliary tree, obstructive cholangiopathy, and a pancreaticobiliary ductal junction anomaly. Infants with a choledochal cyst usually present with jaundice and acholic stools. The presentation may be similar to that of biliary atresia. Choledochal cysts are classified on the basis of their location, the cholangiographic morphology, and the number of intrahepatic and extrahepatic duct cysts. The most widely used classification system is by Todani and colleagues.[51]

Sonography, the initial imaging method in the evaluation of choledochal cysts, is used to evaluate the size and location of the cyst and to image the entire intrahepatic and extrahepatic biliary tree. Choledochal cysts are anechoic with a thin lining at sonography. The appearance ranges from that of a focal, rounded cyst (Fig. 37-33) to that of fusiform dilation of the common bile duct and possibly the extrahepatic biliary tree (Fig. 37-34).[29] The dilated segment of extrahepatic biliary tree may be eccentric relative to the adjacent ductal system.

CT and MRI are also useful in the evaluation of choledochal cysts. They are helpful in better defining the biliary origin of the cyst, particularly with large lesions. It may be difficult to determine the site of origin of large cysts by sonography. In addition, CT and MRI can delineate precisely the relationship between the cyst, the pancreatic head, and the porta hepatis, which is useful in preoperative planning.

Cholelithiasis

The presence of gallstones is not rare in infants. Approximately 10% of all cases of gallstones in children occur in the first 6 months of life. Neonatal cholelithiasis is associated with total parenteral nutrition, furosemide therapy, dehydration, infection, hemolytic anemia, and short-gut syndrome. Neonates who undergo parenteral nutrition are at greatest risk, and gallstones have been reported in up to 40% of such infants. The typical sonographic appearance of a gallstone is an echogenic, intraluminal structure that causes distal acoustic shadowing and moves with patient position.

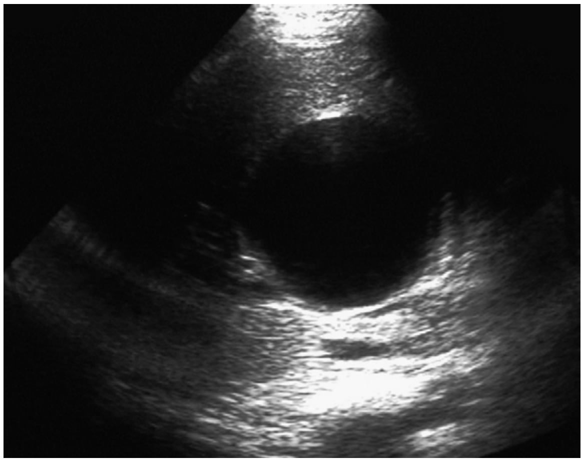

Figure 37–33. Choledochal cyst. Transverse sonogram through the porta hepatis demonstrates focal cystic dilation of the biliary tree.

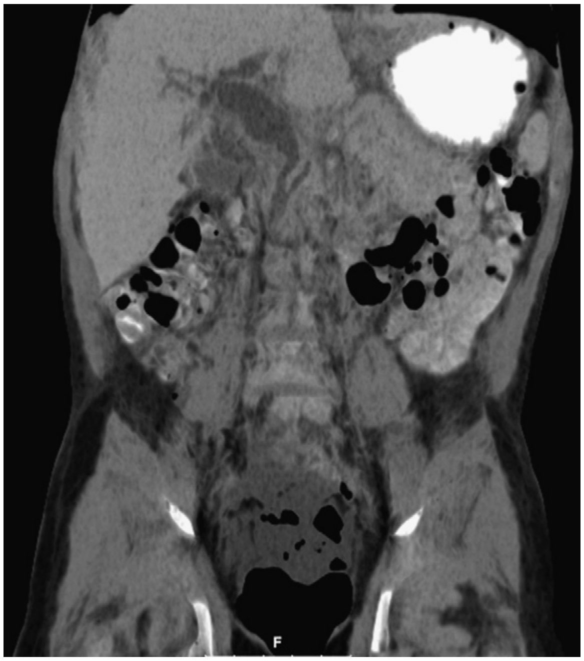

Figure 37–34. Choledochal cyst. MRI through the liver shows fusiform dilation of the biliary tree.

Hepatic Calcifications

Hepatic calcifications can occur in a variety of conditions. These include prenatal and postnatal infections, meconium peritonitis, trauma, and neoplasms. They may also result from umbilical venous catheter complications.

Liver Tumors

Benign liver tumors are more common than malignant tumors. The most common benign tumors are hemangiomas and hemangioendotheliomas. MRI is the imaging examination of choice for these lesions. They appear hypointense on T1-weighted images and hyperintense on T2-weighted images (Fig. 37-35). Primarily hepatic neoplasms are unusual in infants. The most common one is hepatoblastoma. It has a variable appearance at cross-sectional imaging ranging from a solitary mass to a multifocal or infiltrative appearance. MRI is becoming the primary tool to define and stage the extent of liver tumors. The most common metastatic tumor of the liver is neuroblastoma.

URINARY TRACT

Sonography is the imaging examination of choice for the initial evaluation of suspected urinary tract abnormalities in infants. Familiarization with the normal appearance of the neonatal kidney at sonography is important because it is different from the appearance in older children. The neonatal kidney typically demonstrates increased parenchymal echogenicity because of the relatively high number of glomeruli and the increased cellularity. Therefore, the renal parenchyma is often isoechoic or hyperechoic relative to those of liver and spleen. The increased parenchymal echogenicity persists until age 3 to 4 months. The neonatal kidney also demonstrates prominent, hypoechoic pyramids because of the larger medullary volume present. This finding may persist until 1 year of age and should not be confused with a dilated collecting system. Finally, the neonatal kidney demonstrates a paucity of sinus fat. Therefore, the central portion will not be echogenic. Renal sinus fat slowly accumulates during childhood.

Small amounts of fluid may be seen in the renal pelvis of infants in the absence of urinary tract pathology. It is generally accepted that fluid in the renal pelvis and an AP diameter of the renal pelvis of less than 5 mm are normal findings.[12,17] A renal pelvic diameter of 5 to 9 mm is characterized as mild pyelectasis. It can be associated with a small amount of fluid in the calices, which is referred to as *caliectasis*. These findings have been reported in 6% of normal neonates,[17] are not associated with obstructive uropathy or vesicoureteral reflux, and have no pathologic significance. Furthermore, the findings usually resolve over the first year of life. Therefore, neonates with a renal pelvic diameter of less than 10 mm are not at increased risk for urinary tract disease and do not require further follow-up. If the renal pelvic diameter is greater than 10 mm, the infant should be evaluated for possible obstructive uropathy.

The neonatal kidney may also demonstrate increased medullary echogenicity in the first week of life (Fig. 37-36).[24,46] This increased medullary echogenicity is a result of transient tubular stasis and should not be confused with medullary nephrocalcinosis or calculi. The findings are usually diffuse

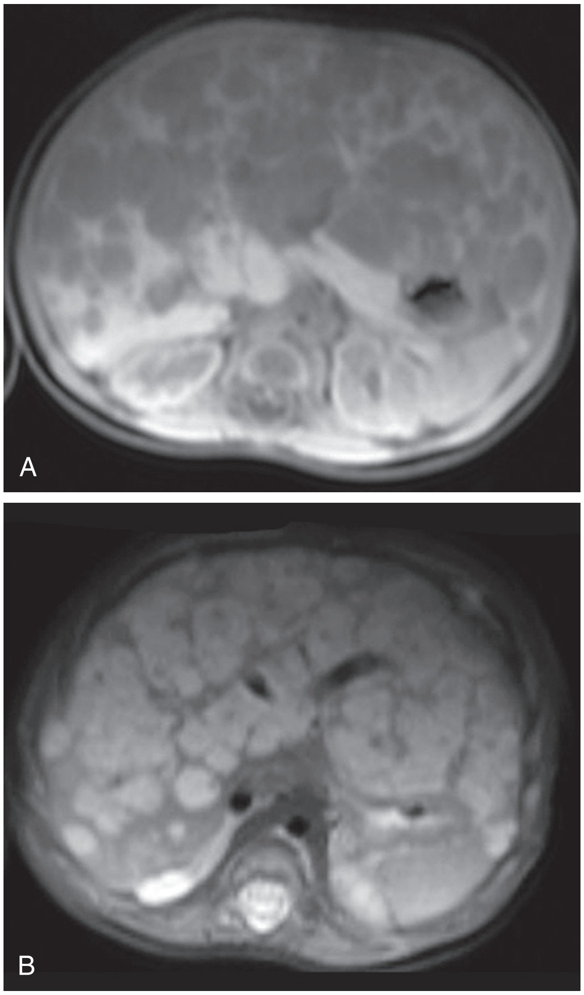

Figure 37–35. Hemangioendothelioma. Axial views through the liver demonstrate a diffuse infiltrative hepatic mass demonstrating low signal on T1-weighted images (**A**) and high signal on T2-weighted images (**B**).

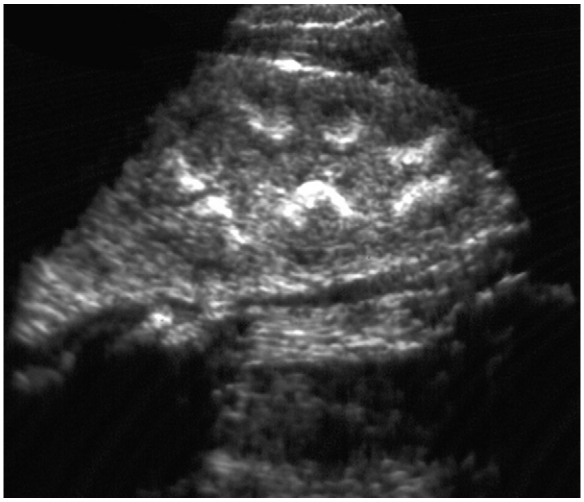

Figure 37–36. Transient increased medullary echogenicity of the newborn. Longitudinal view through the right kidney in a 2-day-old infant demonstrates increased medullary echogenicity. The distribution is bilateral and symmetric. The findings had resolved by the follow-up examination 2 weeks later.

and bilateral, although they may be asymmetric or focal. The finding is usually referred to as *transient increased medullary echogenicity of the newborn* and usually resolves by 2 weeks of life. It is not associated with any long-term renal dysfunction.

Obstructive Uropathy

The most common cause of urinary tract obstruction in infants is ureteropelvic junction (UPJ) obstruction. It is commonly identified initially on prenatal imaging, but infants may also present after birth with a palpable abdominal mass representing an enlarged, hydronephrotic kidney. Sonography is the initial diagnostic examination in children with suspected UPJ obstruction. The sonographic findings include dilation of the intrarenal collecting system without ureteral dilation (Fig. 37-37).[8] The obstruction is bilateral in one fourth to one third of patients. Although the diagnosis of UPJ obstruction can be made with a high degree of certainty with sonography, renal scintigraphy is needed to quantify the degree of obstruction, and it also is used to determine renal function. The scintigraphic appearance of UPJ obstruction involves progressive increase in radionuclide activity within the renal collecting system and delayed excretion. UPJ obstruction may be associated with vesicoureteral reflux, so the imaging evaluation of infants with the condition should include a voiding cystourethrogram.

Posterior urethral valves are the most common cause of lower urinary tract obstruction and the leading cause of end-stage renal disease in boys. The diagnosis is also often made at prenatal imaging, but it is not unusual for the initial diagnosis of this condition to occur after birth. Clinical findings include a palpable abdominal mass representing enlarged kidneys or bladder (or both), voiding abnormalities, or symptoms related to urinary tract infection. The initial imaging examination is sonography, which demonstrates bilateral hydroureteronephrosis and a dilated or thick-walled bladder.[37] The diagnosis is confirmed with a voiding cystourethrogram. The findings of this procedure include a dilated posterior urethra and diminution of the urethral caliber distal to the valves (Fig. 37-38).[37] There may be associated vesicoureteral reflux.

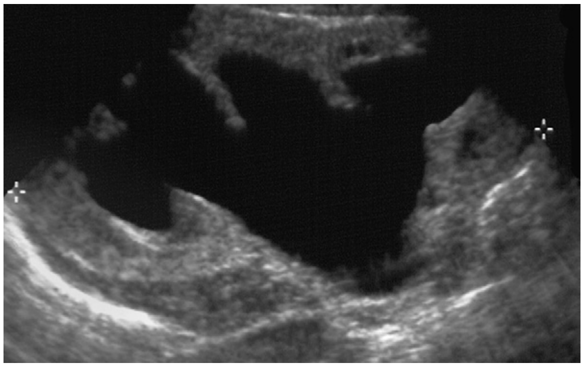

Figure 37–37. Ureteropelvic junction obstruction. Longitudinal view through the right kidney demonstrates marked dilation of the right intrarenal collecting system. The right ureter was not dilated.

Multicystic Dysplastic Kidney

Multicystic dysplastic kidney is the result of an insult in early embryologic development that leads to pelvoinfundibular atresia. The proximal ureter, renal pelvis, and infundibula are all atretic. Subsequently, there is cystic dilation of the collecting tubules, with formation of cystic spaces. There is no identifiable pelvocaliceal system or normal renal parenchyma. Infants with multicystic dysplastic kidney usually present with a palpable flank mass. The two most common flank masses in the newborn are of renal origin: hydronephrosis and multicystic dysplastic kidney.

Sonography is the initial examination of choice in the evaluation of a suspected abdominal mass. The sonographic criteria for diagnosing a multicystic dysplastic kidney include multiple oval or round cysts that do not communicate and absence of renal parenchyma (Fig. 37-39).[48] In most cases, there are multiple cysts, but in a small subset of instances, a

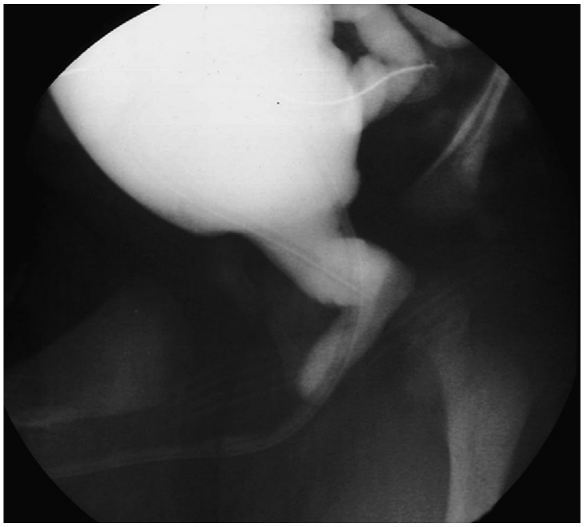

Figure 37–38. Posterior urethral valves. Lateral image from a voiding cystourethrogram shows a dilated posterior urethra and a normal-caliber anterior urethra.

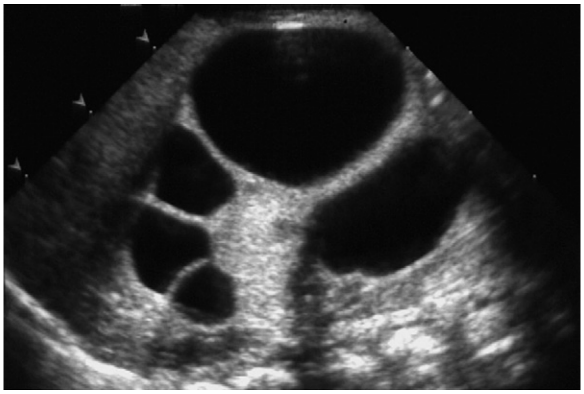

Figure 37-39. Multicystic dysplastic kidney. Longitudinal view through the right renal fossa demonstrates multiple cysts of varying sizes that do not communicate with one another.

single cyst is noted. The natural history of the disease on sonographic follow-up is a gradual decrease in the number and size of the cysts over several months or years as the cyst fluid resorbs.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease is an inherited disorder characterized by nephromegaly, microscopic or macroscopic cystic dilation of the renal collecting system, and periportal hepatic fibrosis. Infants with this disease typically present with palpable abdominal masses or with renal insufficiency. The characteristic sonographic appearance includes enlarged, hyperechoic kidneys bilaterally. Renal enlargement is usually symmetric. The cysts are typically too small to be visualized at sonography. However, the multiple interfaces associated with the cystic dilation of the renal collecting ducts result in increased renal parenchymal echogenicity (Fig. 37-40). In addition, a peripheral hypoechoic rim may be noted along the periphery of the kidney, representing remnants of compressed normal renal cortex.

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease is primarily a disease of adults. It is rarely noted in the neonatal period. The characteristic sonographic appearance includes enlarged, hyperechoic kidneys with macrocysts bilaterally. Macrocysts may be seen rarely in the neonatal period.

Renal Vein Thrombosis

Renal vein thrombosis in infants is associated with hemoconcentration due to dehydration, sepsis, and maternal diabetes mellitus. It may also be seen in association with indwelling umbilical venous catheters in infants who develop thrombi in the inferior vena cava. The clinical presentation includes a palpable mass representing an enlarged kidney, renal insufficiency, hematuria, or hypertension.

Doppler sonography is the examination of choice for the evaluation of suspected renal vein thrombosis. The sonographic findings vary depending on the extent and duration of renal venous occlusion. Sonographic findings include the presence of echogenic filling defects in the main renal vein and absence or diminution of renal venous flow surrounding the thrombus.[22] The venous outflow obstruction results in diminution of ipsilateral renal arterial flow, which in turn results in narrowing of the systolic peak and reduction or reversal of diastolic flow with an elevated resistive index in the ipsilateral renal artery.[33] Enlargement of the involved kidney with diffuse increase in parenchymal echogenicity and loss of corticomedullary differentiation is also typically seen in the acute period. Over the next several weeks, the renal parenchymal echogenicity of the involved kidney becomes heterogeneous and renal size diminishes.

Nephrocalcinosis

Nephrocalcinosis refers to the deposition of calcium in the renal parenchyma. It most commonly affects the renal pyramids and medulla, in which case it is referred to as *medullary nephrocalcinosis*. Hypercalciuria is an important precursor for the development of nephrocalcinosis. Most cases of medullary nephrocalcinosis in neonates are the result of furosemide therapy. Furosemide results in increased calcium excretion. It may also be seen in association with hypervitaminosis D and distal renal tubular acidosis. Most infants are asymptomatic.

Sonography demonstrates increased echogenicity in the normally sonolucent renal pyramids in patients with medullary nephrocalcinosis (Fig. 37-41).[49] Acoustic shadowing does not usually occur. Medullary nephrocalcinosis is typically seen diffusely throughout both kidneys. Sonography is usually used to monitor progression of disease or improvement. Nephrocalcinosis associated with furosemide therapy gradually resolves after the medication is stopped.

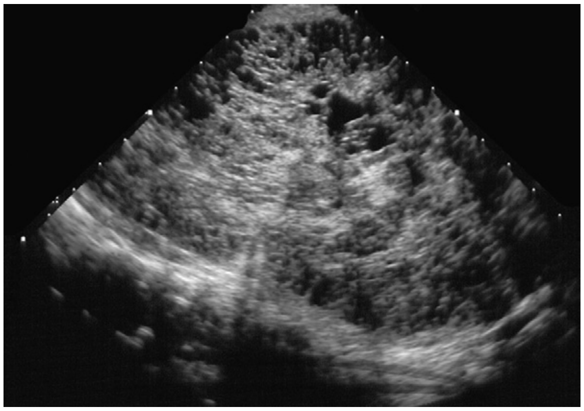

Figure 37–40. Autosomal recessive polycystic kidney disease. Longitudinal view through the right kidney demonstrates renal enlargement. Also note numerous small cysts diffusely.

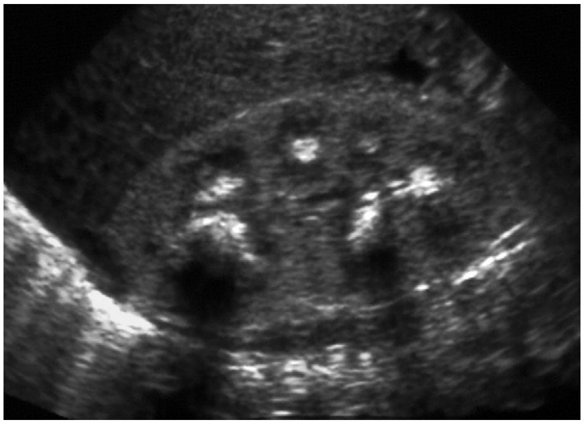

Figure 37–41. Medullary nephrocalcinosis. Longitudinal view through the right kidney in a 3-month-old child who had previously been treated with furosemide demonstrates increased medullary echogenicity indicative of medullary nephrocalcinosis.

ADRENAL

Adrenal Hemorrhage

Adrenal hemorrhage is the most common cause of a neonatal adrenal mass. Right-sided hemorrhage occurs far more commonly than left-sided hemorrhage. Neonates are at increased risk for adrenal hemorrhage because of the relatively large size and increased vascularity of the gland in this age group. Conditions associated with adrenal hemorrhage include perinatal asphyxia, sepsis, coagulation disorders, hypotension, and surgery. Clinical manifestations are typically seen only when there is diffuse, bilateral gland involvement, resulting in adrenal cortical insufficiency.

Sonography is usually the initial imaging examination of choice in the evaluation of suspected adrenal hemorrhage. The sonographic appearance of adrenal hemorrhage is that of an oval or triangular solid mass of variable echotexture.[19] There may be focal or diffuse obliteration of one or both adrenal limbs. Unilateral hemorrhage is more common than bilateral hemorrhage. Adrenal calcification may develop weeks to months after the hemorrhage. Large adrenal hemorrhages may be difficult to differentiate from tumor, particularly if calcification is already present. In such cases, serial follow-up is useful. Typically, adrenal hemorrhages gradually decrease in size over several weeks.

Neuroblastoma

Neuroblastoma is the most common adrenal neoplasm in children. It occasionally manifests in the newborn period. The usual clinical presentation is that of a palpable abdominal mass. Sonography is usually the initial imaging examination of choice. A normal ultrasound result is useful in excluding a mass. Approximately two thirds of abdominal neuroblastomas arise from the adrenal gland. Therefore, the most frequent sonographic appearance is that of a solid, suprarenal mass. It is typically infiltrative with poorly defined borders and heterogeneous in echotexture. Calcifications are noted in approximately two thirds of patients. If a mass is identified at sonography, cross-sectional imaging with CT or MRI is performed for a more precise characterization of the organ of origin and for staging (Fig. 37-42).

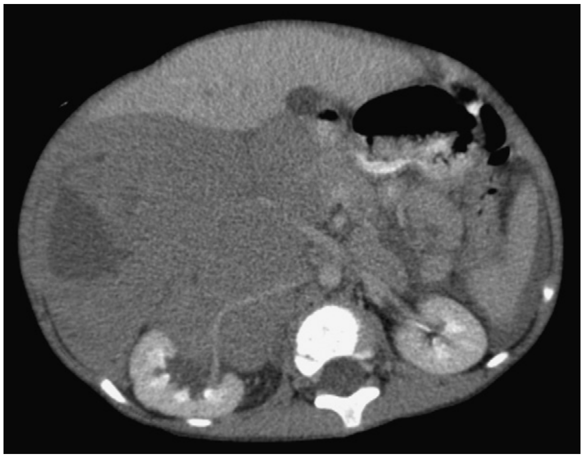

Figure 37–42. Neuroblastoma. CT scan through the upper abdomen demonstrates a large, infiltrative mass originating from the right adrenal gland.

BRAIN

Sonography is the primary means of evaluating intracranial pathology in infants. It is performed through the anterior fontanelle with a 5- to 10-MHz sector transducer. Routine imaging is performed in the coronal and sagittal planes. The advantages of sonography are that it can be performed at the bedside, patients do not require sedation, and it is a useful modality for the evaluation of germinal matrix hemorrhage, which is the most common indication for neuroimaging in infants. However, the ability of sonography to evaluate parenchymal, subarachnoid, and subdural abnormalities is limited. CT and MRI provide accurate depiction of parenchymal, subarachnoid, and subdural disease, and they are more sensitive in the detection of germinal matrix hemorrhage than sonography. In addition, MRI provides detailed anatomic information of intracranial and extracranial vascular anatomy. A major disadvantage of both CT and MRI is that they cannot be performed portably in most settings. Also, MRI may require patient sedation.

Germinal Matrix Hemorrhage

Germinal matrix hemorrhage is seen primarily in premature infants. The infants at highest risk are those with a gestational age of less than 32 weeks or a birthweight of less than 1500 grams. Most hemorrhages occur by the first week of life. The site of origin for germinal matrix hemorrhage is the caudothalamic groove, an area bordered by the ventricular surface of the caudate nucleus and the thalamus. It is an extremely vascular area and, in the premature infant, is composed of thin-walled blood vessels with little surrounding connective tissue. Therefore, conditions that lead to increased blood flow predispose to hemorrhage.

The classification system for germinal matrix hemorrhage was initially described by Papille and colleagues.[44] Their grading system is based on the presence of subependymal and intraventricular hemorrhage, ventriculomegaly, and parenchymal abnormalities. Grade 1 is subependymal hemorrhage only; grade 2 is subependymal and intraventricular hemorrhage; grade 3 is subependymal and intraventricular hemorrhage and ventriculomegaly; and grade 4 is subependymal and intraventricular hemorrhage, ventriculomegaly, and intraparenchymal abnormalities.[44] Subsequent systems for classification reflect that parenchymal hemorrhage is not a direct extension from intraventricular hemorrhage. It classifies periventricular parenchymal abnormalities as periventricular hemorrhagic infarctions. (See also Chapter 40, part 3)

At sonography, a grade 1 hemorrhage appears as a subependymal echogenic mass inferolateral to the frontal horn of the lateral ventricle (Fig. 37-43). If the subependymal hemorrhage is large, it may compress the ipsilateral lateral ventricle. In grade 2 hemorrhage, blood ruptures through the ependyma and is seen within the ventricle (Fig. 37-44).[10] Occasionally it is difficult to distinguish intraventricular hemorrhage from choroid plexus. If intraventricular

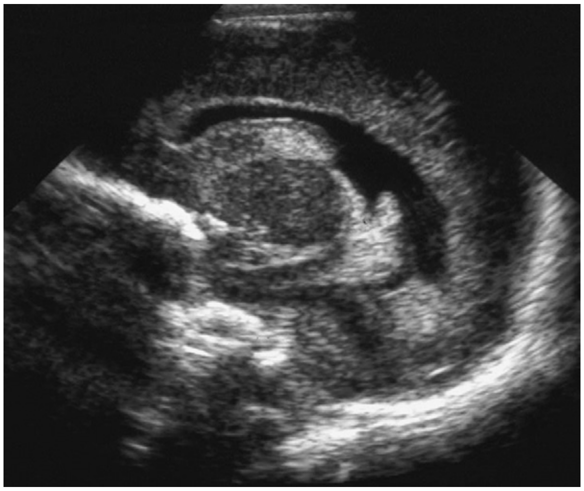

Figure 37–43. Grade 1 hemorrhage. Longitudinal view through the right lateral ventricle demonstrates a subependymal hemorrhage.

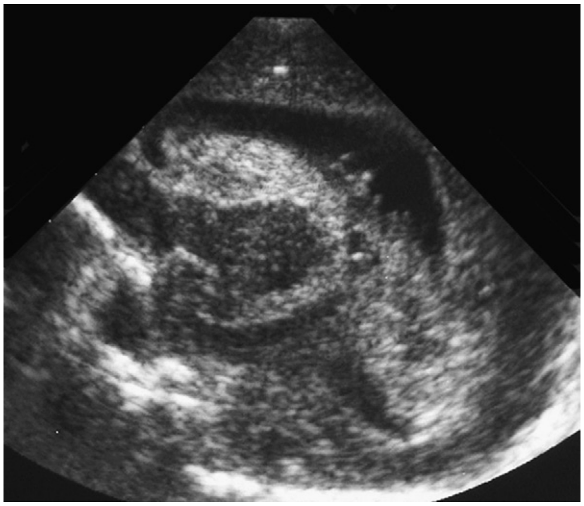

Figure 37–45. Grade 3 hemorrhage. Longitudinal view through the left lateral ventricle shows intraventricular hemorrhage and ventriculomegaly.

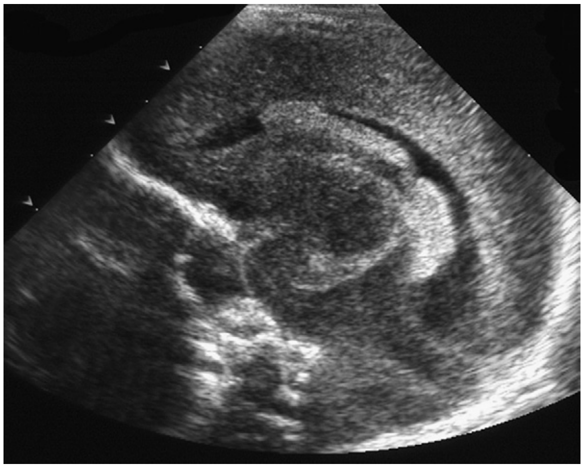

Figure 37–44. Grade 2 hemorrhage. Longitudinal view through the right lateral ventricle demonstrates subependymal and intraventricular hemorrhage.

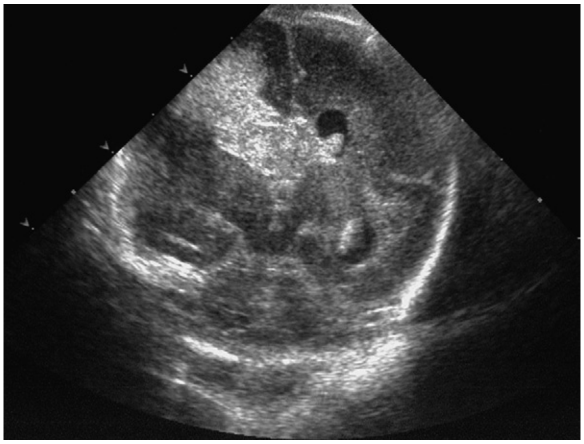

Figure 37–46. Grade 4 hemorrhage. Longitudinal view through the right lateral ventricle demonstrates intraventricular hemorrhage and echogenic parenchymal abnormality, representing hemorrhage or infarct, or both.

echogenicity is noted anterior to the foramen of Monro, or if the choroid plexus appears asymmetrically enlarged or irregular, it usually signifies intraventricular hemorrhage. In grade 3 hemorrhage, the intraventricular hemorrhage expands one or both ventricles, resulting in ventriculomegaly (Fig. 37-45). Grade 4 hemorrhage is characterized by echogenic periventricular abnormalities (Fig. 37-46).[10] Most of these areas represent hemorrhagic venous infarcts that result from compression of periventricular veins by the subependymal hemorrhage. The grade of the germinal matrix hemorrhage has been shown to affect neurodevelopmental outcome. The developmental outcome in infants with grades 3 and 4 hemorrhage is worse than that in those with grades 1 and 2.[35]

Ventriculomegaly is a frequent consequence of intraventricular hemorrhage. It usually results from an obliterative arachnoiditis or from an intraventricular obstruction from clot or debris. The ventriculomegaly may be present initially or may be delayed by several weeks. Typically, the trigones and occipital horns of the lateral ventricles dilate before the frontal horns, and the lateral ventricles may dilate alone or to a greater degree than the third and fourth ventricles. Serial sonographic evaluation is performed in infants with a germinal matrix hemorrhage because of the risk of developing hydrocephalus. On serial sonographic follow-up, the ventriculomegaly frequently resolves or remains static. Progressive hydrocephalus requiring shunting is seen in less than 10% of cases.

Periventricular Leukomalacia

Periventricular leukomalacia (PVL) represents infarction of deep white matter adjacent to the trigones and frontal horns of the lateral ventricles. It is frequently associated with intraventricular hemorrhage—approximately half of infants with PVL have intraventricular hemorrhage. Sonography results are often normal early in the course of PVL and thus are insensitive for the early diagnosis. The earliest sonographic abnormality is increased periventricular echogenicity (Fig. 37-47). With progression of disease, cavitation occurs, resulting in parenchymal cystic areas (Fig. 37-48). These areas may communicate with the ipsilateral lateral ventricle.

CT is more sensitive than sonography for detecting the hemorrhagic component of PVL.[47] Decreased attenuation of white matter is noted at CT unless the ischemic area is accompanied by hemorrhage. The latter condition is associated with increased attenuation. MRI is the most sensitive imaging modality for the assessment of PVL.[7,47] Peritrigonal areas of hyperintensity are seen on T2-weighted images. The corpus callosum is often thinned or atrophic. In addition, irregularity of the lateral ventricular contour and asymmetric ventricular enlargement may be noted.

Lenticulostriate Vasculopathy

Lenticulostriate vasculopathy represents mineralized deposits in arterial walls and perivascular infiltration of mononuclear cells secondary to inflammatory or necrotizing vasculitis. These deposits are predominantly seen surrounding the lenticulostriate branches of the middle cerebral arteries. Lenticulostriate vasculopathy has been associated with various congenital infections, including syphilis, rubella, toxoplasmosis, and cytomegalovirus. It also has been associated with chromosomal abnormalities, fetal alcohol syndrome, bacterial meningitis, and perinatal asphyxia. Lenticulostriate vasculopathy is believed to represent a nonspecific response to vascular injury. The appearance at sonography is of linear or branching areas of echogenicity that may be seen in the thalami and basal ganglia (Fig. 37-49). The abnormalities are more commonly bilateral than unilateral. The initial observation of lenticulostriate vasculopathy may be in the first week of life, but more frequently it is noted at several weeks or months of age.

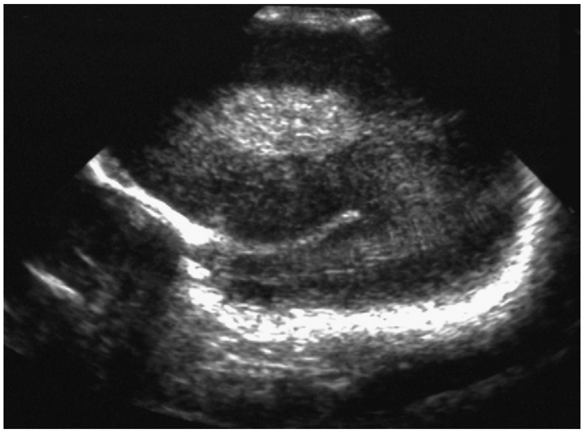

Figure 37–47. Periventricular leukomalacia. Longitudinal view through the right hemisphere demonstrates increased echogenicity in the frontal-parietal region.

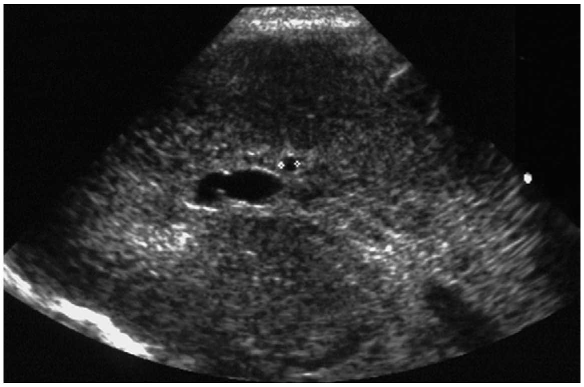

Figure 37–48. Periventricular leukomalacia. Longitudinal view through the right hemisphere in same infant 2 weeks later demonstrates several cysts in the frontal-parietal region.

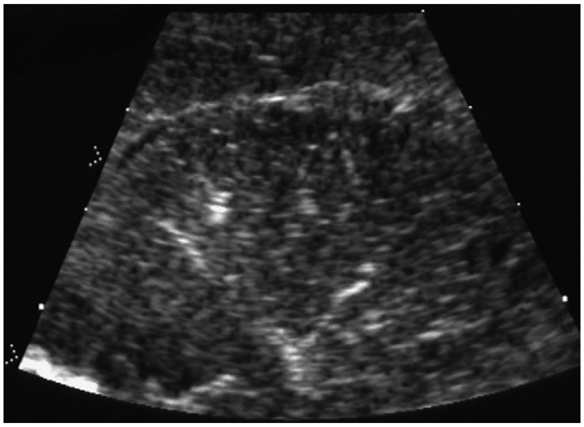

Figure 37–49. Lenticulostriate vasculopathy. Longitudinal view through the right thalamus demonstrates branching linear areas of echogenicity.

SPINE

Tethered Cord

A tethered cord is defined as a low position of the conus medullaris and thickening of the filum terminale. It is seen in association with various syndromes, spina bifida, meningocele, terminal lipoma, diastematomyelia, and sacral dimple. Sonography is the primary screening examination for the evaluation of a tethered cord. A high frequency linear transducer is utilized. The diagnosis is made when the conus medullaris terminale terminates at or below the L3 vertebrae. MRI is typically performed in all abnormal cases to better evaluate for associated abnormalities.

SKELETAL

Skeletal radiography is usually the initial imaging examination in the evaluation of suspected skeletal pathology in infants. Skeletal scintigraphy is useful in the evaluation of disseminated infection, neoplasm, or trauma. CT and MRI are useful for the precise characterization of infection.

Intrauterine Infection

Intrauterine infection may result in skeletal changes. Congenital rubella and cytomegalovirus infection result in metaphyseal lesions with vertical striations that resemble a celery stalk. Congenital syphilis results in single or multifocal metaphyseal lesions representing osteomyelitis. The fetus is typically infected during the third trimester; therefore, changes of acute and chronic osteomyelitis may be noted. The metaphyseal lesions vary from radiolucent transverse metaphyseal bands to actual destruction and fragmentation of bone. Whenever the destructive changes occur bilaterally in the upper medial tibiae, the term *Wimberger sign* is applied. Associated periostitis may also be noted.

Postnatal Infection

Neonatal osteomyelitis is typically caused by staphylococci, streptococci, or *Candida*. There is an increased risk of osteomyelitis in preterm infants. The infection involves the metaphyses of long bones and produces focal lytic areas at radiography. Associated soft tissue edema may be noted. Skeletal radiography remains the most common mode of assessing suspected osteomyelitis. The earliest radiographic finding is soft tissue swelling that results in displacement or obliteration of fat planes. Bony changes include poorly defined metaphyseal lucency with progressively increased bony destruction. Bony changes may not be present in the first 7 to 10 days; therefore, skeletal radiography is not a sensitive modality early in the disease. Bone scanning may be useful to characterize all of the lesions when the involvement is multifocal. CT and MRI are also useful in the early detection of osteomyelitis; also, they demonstrate adjacent soft tissue abnormalities. In infants, osteomyelitis is often seen in conjunction with septic arthritis because the metaphysis and epiphysis have contiguous blood supplies.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip results from abnormal position of the femoral head relative to the acetabulum, which results in abnormal growth of both components. Excessive ligamentous laxity plays an important contributing role. It is more common in girls than in boys. It is associated with breech deliveries and oligohydramnios. Sonography is the examination of choice for screening evaluation in the neonatal period. Sonography is able to visualize directly the cartilaginous components of the hip, determine the position of the femoral head and depth of the acetabulum, and evaluate dynamic instability. Hip sonography evaluates acetabular morphology, angle of the acetabular roof, coverage of the femoral head, and dynamic subluxation during stress maneuvers (Fig. 37-50).

Congenital and Developmental Anomalies

Skeletal radiography plays a primary role in the evaluation of congenital and developmental abnormalities of the axial skeleton and extremities. Imaging of a specific site is performed when there is a localized concern, such as craniosynostosis, congenital spinal deformity, radial ray abnormality, or scapular nondescent. When a skeletal dysplasia is suspected, a skeletal survey is performed. The skeletal survey should include individual AP views of the femurs, tibias, and fibulas; humeri, radii, and ulnas; and hands, feet, pelvis, chest, and abdomen. A lateral view of the skull should also be included.

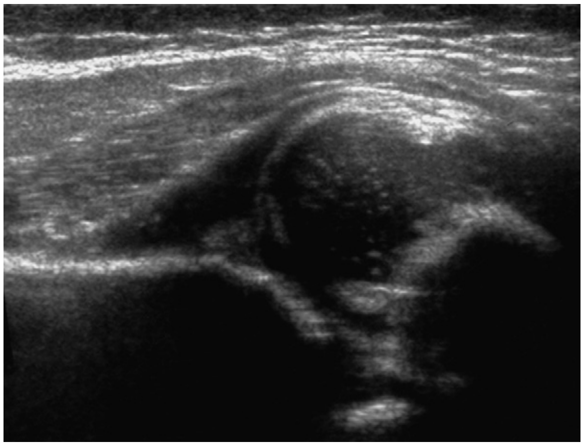

Figure 37–50. Developmental dysplasia of the hip. Longitudinal view through the left hip demonstrates a shallow left acetabulum.

Trauma

The most common cause of neonatal skeletal injury is as a result of difficult or traumatic delivery. The most common site of fracture is the clavicle. Long bone fractures may also be noted, including physeal injury. Neonatal fractures occurring from intentional trauma are uncommon.

Rickets

Rickets occurs as a result of a relative or absolute deficiency of vitamin D, which in turn leads to a failure of normal mineralization of developing bone. The radiologic findings of rickets precede clinical manifestations. The radiographic abnormalities are seen in the distal metaphyses and include cupping, fraying, and irregularity. Widening of the physis and loss of definition of the epiphyses may also be noted. There is also diffuse demineralization. Because the radiographic abnormalities are seen in all of the distal metaphyses, it is not necessary to obtain radiographs of multiple joints. A single AP view of the wrist or knee is sufficient to demonstrate the abnormality.

FUTURE DIRECTIONS

The use of diagnostic imaging in infants and neonates continues to evolve because of advances in imaging technology. Over the past decade, advancements in prenatal imaging with sonography and MRI have had a tremendous impact on the early diagnosis and treatment of many pathologic conditions that affect infants and young children. This, in turn, has greatly enhanced the therapeutic options available for such patients and access of MRI scanners to neonates has been optimized. The continued refinement of those modalities will result in earlier and more precise diagnosis of many of these conditions. Also, the introduction of multislice CT scanning has allowed enhanced imaging in neonates by facilitating faster scan times (thus decreasing the need for sedation) and thinner imaging sections (thus allowing improved visualization of normal and abnormal anatomy in smaller patients). Advancements in duplex and color Doppler technology—the development of higher-frequency transducers and the ability to visualize lower velocities of blood flow in smaller vessels—are also expanding the diagnostic capability in infants and neonates. In the future, there will likely be an increasing focus on functional imaging modalities, such as positron-emission tomography scanning, as diagnostic imaging continues to evolve from primarily evaluating anatomy to also assessing function.

CHAPTER 38

Pharmacology

PART 1

Developmental Pharmacology

Jacquelyn McClary, Jeffrey L. Blumer, and
Jacob V. Aranda

PHARMACOLOGY OF THE MATERNAL-FETAL-PLACENTAL UNIT

Three aspects of pharmacotherapy must be considered when designing a therapeutic drug regimen (Fig. 38-1). In general, pharmacokinetics includes the processes of drug absorption, distribution, metabolism, and excretion, whereas pharmacodynamics refers to the mechanisms of drug action and drug safety. The pharmaceutic aspects of drug therapy pertain to the actual formulation of the drug (e.g., tablet, liquid, suspension, capsule), including its inert ingredients. In therapeutics, if, for a given disorder and a given patient, a drug can be identified that has favorable characteristics in each of these three areas, therapy will be effective.

The identification of such a drug is usually a fairly complex problem that must take into account all the individual differences in physiology and biochemistry that may affect drug disposition. In addition, the pathophysiologic state, disease severity, and changes in the disease process must be considered during therapy. This complex set of issues must be assessed each time a patient is evaluated.

Pregnancy is a pathophysiologic state that further increases the complexity of drug regimen design. Instead of dealing with the pharmacokinetic and pharmacodynamic processes in a single individual, one must consider three distinct but intimately interconnected compartments—the mother, the fetus, and the placenta (Fig. 38-2).[14] Changes in each of these compartments occur as pregnancy progresses. Careful attention must be paid to these changes in order to optimize the safety and efficacy of drug therapy for both mother and fetus.

Maternal Drug Disposition During Pregnancy

Pregnancy is a period of change in female physiology. A number of important changes directly influence drug disposition in both the maternal and fetal environments (Table 38-1).

DRUG ABSORPTION

Among the changes seen during pregnancy that potentially affect drug disposition, the decrease in intestinal motility and delayed gastric emptying are prominent. These changes may reduce the rate of absorption of orally administered medications. As a result, the observed peak maternal serum drug concentration is blunted, delayed, or both. In most cases, these effects are of little clinical consequence in the treatment of maternal disorders because they do not affect the steady-state concentration. However, in the case of medications extensively metabolized by enzymes within the gastrointestinal tract (cyclosporine, carbamazepine, tacrolimus), the increased gastric transit time can result in decreased maternal bioavailability.

An increase in gastric pH, resulting from decreased gastric acid secretion and increased mucus production during pregnancy, can also affect oral absorption. Under these circumstances, the ionization of weak acids (aspirin) is increased, which leads to decreased absorption, whereas weak bases (narcotic analgesics) are more likely to be un-ionized and more readily absorbed. Again, the effect on the mother is likely to be negligible because steady-state concentrations are not expected to be significantly altered.[15] The clinical significance relative to fetal distribution is also minimal because steady-state maternal drug concentration appears to be the most important determinant of the extent of drug diffusion from the maternal to fetal compartment. The alterations in peak serum drug concentrations and time to peak concentrations do not influence the overall fetal drug exposure.

Absorption of aerosolized (inhaled) medications into systemic circulation may be greater during pregnancy because of increases in minute ventilation. Similarly, maternal exposure to environmental toxins and pollutants also increases. On average, maternal tidal volume increases about 39%, with an accompanying average increase in minute ventilation of about 42% during pregnancy. The primary determinant of drug exposure after aerosolized drug administration is minute ventilation, not the absolute dose of the medication per exposure. This fact is of the greatest significance for medications that are characterized by excellent bioavailability after inhalation (e.g., adrenergic receptor agonists [epinephrine, albuterol], dexamethasone). It is unknown whether the enhanced pulmonary exposure during pregnancy poses any real threat to the mother or the fetus. Some investigators have attempted to extrapolate the differences in exposure rates

between men and women for certain environmental diseases (e.g., silicosis) based on enhanced exposure during pregnancy. However, because this aspect of possibly enhanced drug exposure has not been specifically studied, its impact on fetal drug exposure remains unknown. Nevertheless, it seems prudent to closely monitor the therapeutic response and systemic effects of aerosolized medications, as well as the amount and types of environmental exposures encountered by pregnant patients.

With respect to percutaneous drug exposure or administration, the differences that occur in peripheral regional blood flow during pregnancy are of particular interest. During pregnancy, the blood flow increases about sixfold in the human hand and about twofold in the human foot, with only small increases observed in the human forearm and leg. These increases in perfusion take on added importance with the increasing number of medications administered topically as either patch formulations or ointments and creams. Although the primary determinants of dermal drug absorption are lipid solubility (stratum corneum and stratum lucidum) and water solubility (stratum granulosum, stratum spinosum, stratum basale, and the basement membrane), exposed surface area and blood flow to the skin are also important components. Although the increases in dermal blood flow are well documented, their impact on drug absorption has not been determined. Moreover, the specific regions that have been reported to receive greater blood flow do not represent the more common sites for the application of patch formulations (e.g., chest, back). Thus, the possibility of enhanced systemic exposure from topically administered medications during pregnancy may be of limited clinical significance, with the exception of the direct application of medications to the hand or foot.

The overall effects of changes in intestinal motility, gastric pH, minute ventilation, and regional blood flow during pregnancy remain largely unknown. It is the steady-state concentration of the drug in the maternal circulation that ultimately determines the amount of the drug available for distribution to the fetal compartment. Because steady-state concentration is more a product of drug clearance than drug absorption, these changes in maternal physiology would be predicted to have little impact on fetal drug exposure. Nevertheless, data are lacking and studies are needed.

DRUG DISTRIBUTION

During pregnancy, several physiologic changes occur that may influence drug distribution (Tables 38-1 and 38-2). Maternal total body water, extracellular fluid, and plasma volume all increase gradually during pregnancy by about 32%, 36%, and 52%, respectively (see Table 38-2). Maternal cardiac output also increases by about 40% to 50% as a result of increases in both heart rate and stroke volume. The increase in body water is the primary reason for the observed decreases in peak drug concentrations with standard dosing of water-soluble drugs. When the drug dose is kept constant in the presence of increasing body water, the drug's apparent volume of distribution (Vd) increases, and steady-state drug concentrations decrease. Such a decrease in steady-state concentrations may alter the therapeutic effect of the drug in the mother and influence the amount of drug available for diffusion across the placenta. Similarly, the increase in cardiac output affects drug transfer by limiting the time a drug resides in the villous space (see placenta) and is available for transfer to the fetus.

Coincident with the changes in body water distribution and cardiac output, the amount of maternal fat increases at a relatively constant proportion to the increase in body weight (see Table 38-2). The result is an increase in Vd for lipophilic drugs and the potential for accumulation within the adipose tissue. Minimal changes in drug efficacy are expected under these circumstances; however, the adipose tissue can act as a reservoir and slowly release the drug into systemic circulation. An increased half-life and prolonged drug effects may be observed.

Complicating the picture even further is the fluctuation in serum proteins during gestation. Both albumin and α_1-acid glycoprotein are decreased during pregnancy, resulting in an increase in the free (active) fraction of various highly protein-bound drugs (phenytoin, diazepam). The unbound drug is not only the active moiety but is also the form that is available for metabolism and elimination by the mother and transfer to the fetus. Unfortunately, the interaction of the free drug with these kinetic processes is often difficult to predict, and close monitoring of maternal efficacy, side effects, and serum concentrations is required.

The overall impact of changes in body composition and protein binding during pregnancy is largely unknown. These changes likely effect both mother and fetus, but the interactions are complex, making predictions regarding their impact speculative at best.

HEPATIC DRUG METABOLISM

Changes in hepatic metabolism during pregnancy affect the normal rate and extent of drug transformation and ultimately renal elimination. Theoretically, during pregnancy, hepatic

blood flow should increase as a result of increased cardiac output. The amount of drug per unit time presented to the liver for metabolism is likely to be increased, and thus drug metabolism is increased. In reality, the potential increase in hepatic blood flow is controversial. Some investigators have shown significant increases in hepatic blood flow after 28 weeks' gestation, whereas others have found no apparent change throughout pregnancy.[4]

Alteration in the activity of hepatic enzymes during pregnancy is less debated. Enzymes from the cytochrome P-450 (CYP) family and those responsible for glucuronidation reactions (UGT) exhibit changes in activity as a result of pregnancy, which can potentially affect maternal and fetal drug exposure (Table 38-3). For example, labetalol is a commonly used antihypertensive agent in pregnant women, and it is extensively metabolized by UGT enzymes that have increased activity during pregnancy. Therefore, as expected, the clearance of labetalol after oral administration is increased during the second and third trimester by as much as 30%, and the half-life is significantly shorter in the pregnant compared with nonpregnant patient.[4] The consequence for the mother is an increase in dose and more frequent dosing intervals.

RENAL EXCRETION

Changes in renal elimination during pregnancy result from the increase in renal blood flow by about 60% to 80% and the increase in glomerular filtration rate by about 50%.[15] As a result, there is enhanced elimination of drugs typically excreted unchanged in the urine (penicillin, digoxin). The lower steady-state concentrations that result are not often clinically significant, and dose adjustments are typically not required.

Placenta

See Chapter 24.

After fertilization, the rapidly dividing conceptus travels down the fallopian tube toward the uterus. By the third day, the mulberry-appearing conceptus divides into about 16 cells and enters the uterus. This stage of embryonic development, called the *morula*, consists of an inner cell mass and a surrounding layer, the outer cell mass. The inner cell mass forms the embryo, whereas the outer cell mass forms the trophoblast, which helps to form the placenta. Once in the uterus, maternal fluids penetrate the zona pellucida and accumulate within the inner cell mass between the cells. This developmental stage represents the first exposure of the conceptus to maternal fluids. Gradually, a cavity (the blastocele) forms, displacing the inner cell mass to one pole of the embryo. These changes signal the blastocytic stage of embryonic development. The zona pellucida disappears, allowing implantation to take place. About the sixth day after fertilization, the trophoblastic cells lining the inner cell mass begin to penetrate the uterine mucosa, attaching the conceptus to the myometrial epithelium. Proteolytic enzymes from the uterine mucosa and the trophoblast probably work in concert to allow the implantation of the zygote. Thus, by the end of the first week after fertilization, the human zygote has passed through the morula and blastocytic stages of development and begun implantation in the uterine mucosa. Up to this point, no interface for maternal-fetal exchange has been established.

By the second week of development, lacunae formed within the trophoblastic cell mass have fused to form interconnected lacunar networks. These lacunae function as early intervillous spaces in the placenta. Maternal blood seeps into and flows slowly throughout the lacunar system, establishing the uteroplacental circulation. About the end of the second week, primary chorionic villi form and begin to differentiate in the placenta. Early in the third week, the mesenchyme grows into the primary chorionic villi, forming a placard of loose connective tissue. Mesenchymal cells in the villi differentiate into capillaries and form arteriovenous networks. Blood vessels from within these maturing villi become connected with the embryonic heart, later establishing the umbilical cord. By the end of the third week, embryonic blood begins to circulate through the capillaries of the chorionic villi, and by the end of the fourth week, the essential elements necessary for physiologic exchange between the mother and the embryo are well established.

From the fourth week of gestation until term, the surface area of the placenta increases dramatically to accommodate the increasing needs of the maturing fetus. The surface area of the villi, which represents the real area for exchange, is about 3.4 m^2 at 28 weeks' gestation, compared with about 12.6 m^2 at term. In contrast, the thickness of the placental membrane decreases with advancing gestation. During late gestation, at about 32 weeks, the fetal capillaries become oriented beneath the thin layers of syncytial trophoblast. In

these areas, the tissue barrier separating the maternal and fetal circulations may be less than 2 μm, and the areas become specialized in the transport functions of the placenta (i.e., rapid diffusion of substances) rather than the metabolic ones. By term, the placenta has only a single cell layer of fetal chorionic tissue separating the fetal capillary endothelium from the maternal blood. This separation, with its loose intercellular connections, presents little hindrance to small molecule transfer. Both the decreasing membrane thickness (from about 50 to 100 μm to 2 to 5 μm at term) and increasing surface area with advancing gestation favor the greater transfer of drugs during late gestation.

IMPORTANT DIFFERENCES BETWEEN HUMAN AND ANIMAL PLACENTAS

As described earlier, the human placenta is a network of specialized cells and tissues whose functional capacity evolves during gestation. These dynamic processes (which most likely vary with the stage of gestation), combined with the ontogeny of placental drug transporters (e.g., carrier protein P-glycoprotein [Pgp]), influence the ability of drugs and other compounds to cross from the maternal to the fetal compartment. Unfortunately, the many medical, ethical, and social barriers that limit our ability to study human placental development necessitate our reliance on the studies of placental mechanics performed in various animal species to model the human system.

Although much has been learned about placental maturation and function from such studies, these data must be extrapolated to the human placenta with extreme caution. It is of the utmost importance to recognize that the cellular arrangement of the human placenta differs markedly from that of many other mammals. The differences in placental structure between humans and other mammals influence the rate at which a compound crosses in either direction and the extent to which it does so. Thus, the placental transfer for a particular drug or substrate defined in the rat or sheep may bear little relation to human placental function and substrate disposition.

Studies that have compared the placental transport function and capacity for specific substrates between humans and various animal species have revealed substantial differences. Some of these differences are most likely due to the anatomic differences between the placentas of humans and various animal species. For example, the placenta in most mammals is classified as chorioallantoic. It includes a chorion vascularized by blood vessels derived from the allantois. Once vascularized, the chorion forms the placenta. In humans, other primates, pigs, and ruminants, a chorioallantoic placenta persists throughout gestation. In contrast, many rodents and lagomorphs have two types of placenta that persist throughout gestation: the chorioallantoic placenta and the inverted yolk sac placenta. The reader who has an in-depth interest in the embryology and structure of the placentas of various animal species is referred to more detailed discussions of this topic.

The impact of these placental differences with regard to drug transfer is best exemplified by the differences in transport mechanisms. In the human placenta, the transfer of most compounds, including drugs, appears to involve simple diffusion. In contrast, in the rodent placenta, active transport mechanisms develop rapidly. Thus, the drug transfer mechanics described in some animal placentas may bear no real relation to the drug transfer dynamics in human placentas.

DRUG TRANSFER ACROSS THE PLACENTA

Very little specific information defines the mechanisms of the processes and extent of drug transfer across the placenta. This circumstance is a direct result of the difficulties inherent in studying the target population and our reliance on data obtained from the models of nonhuman systems. It is difficult to obtain not only general information relative to drug disposition at the human maternal-placental-fetal interface (i.e., to what extent an administered dose of a drug crosses the placenta), but also specific information concerning the processes involved in drug disposition by the placenta, (i.e., the rate and the extent to which the placenta metabolizes drugs).

A number of interdependent variables influence the rate and extent of drug transfer across the placenta from the maternal to the fetal compartment. Most investigators and clinicians believe that the vast majority of compounds found in the maternal circulation will cross the placenta and enter the fetal compartment. Therefore, the fundamental questions are about the rate and extent of this activity. Unfortunately, even today, this information is only partially available for just a few chemical entities. Similarly, the mechanisms by which drugs are transferred across the placenta are not always clear, and more than one type of transfer may be involved.

The possible modes of drug transfer across the placenta are listed in order of importance in Box 38-1. For most drugs and other compounds, it is presumed that the primary mode of transfer is by simple, passive, nonionic diffusion, which requires no energy. Pinocytosis and phagocytosis require energy and likely occur much too slowly to have any significant impact on drug transfer, whereas facilitated and active transport play a role for some drugs.

Corticosteroids are an example of a drug class that undergoes facilitated diffusion. No energy is required to transfer steroids across the placenta, but the steroid must form a complex with a specific carrier on the placenta in order to be transferred from maternal to fetal circulation. Active transport occurs in a similar way, but energy is required for active transport to take place. Valproic acid is thought to be at least partially transferred through the active transport mechanism.[45] Another important aspect of active transport involves the efflux of drugs back to maternal circulation subsequent to binding with a carrier on the placenta. Digoxin is one such drug that binds to the carrier protein Pgp.[22] Pgp is expressed on the maternal side of the placental-trophoblastic layer, where it mediates active efflux from the fetal compartment.

BOX 38–1 Mechanisms of Drug Transfer Across the Human Placenta

Simple diffusion
Facilitated transport
Active transport
Pinocytosis (phagocytosis)

This efflux is unidirectional from the fetal to maternal circulation and is probably responsible for the removal of a number of highly lipid-soluble compounds and drugs from the fetal compartment.[49]

As stated, most drugs are transported across the placenta by simple diffusion, and the factors that influence this process have been more extensively evaluated than those affecting the other transport mechanisms discussed. Simple diffusion is described by the Fick equation as follows:

$$\text{Rate of diffusion} = \text{K} \times \text{A}\ (\text{C}_\text{m} - \text{C}_\text{f})/\text{d}$$

where K is the diffusion constant of the drug, which is dependent on the drug's physicochemical characteristics; A is the surface area of the membrane to be traversed; C_m and C_f are the concentrations of the drug in maternal and fetal blood, respectively; and d is the thickness of the membrane to be traversed. Thus, $\text{C}_\text{m} - \text{C}_\text{f}$ represents the concentration gradient across the placenta, which is primarily regulated by the surface area (A) and thickness (d) of the placenta. As previously mentioned, changes in these characteristics as pregnancy progresses allow for easier transfer of drugs from maternal to fetal circulation.

Other factors important to drug transfer across the placenta include differences between the maternal and fetal osmotic pressures and pH, as well as changes in uterine or placental blood flow. Under normal circumstances, the maternal osmotic pressure is higher than that in the fetal compartment, and a pH difference of 0.1 to 0.15 unit exists between the fetal and maternal blood (i.e., fetal umbilical blood is –0.1 unit of pH lower than maternal blood). If alterations in either the osmotic pressures or pH occur, drug transfer will be affected. With regard to changes in blood flow, the placental flow increases from 50 mL per minute at 10 weeks to 600 mL per minute at term, whereas uterine blood flow approaches 150 mL/kg per minute of newborn body weight at term.[45] Depending on the physicochemical characteristics of the drug, blood flow may have an important influence on the rate and amount of drug transfer.

The important physicochemical characteristics that influence passive drug transfer across membranes (i.e., placenta), as represented by K in the Fick equation, are outlined in Box 38-2. The characteristics that facilitate placental transfer include high lipid solubility, the un-ionized form under physiologic and pathophysiologic conditions, low molecular weight (<500 daltons), and low protein binding. Very few clinically important drugs meet all these "ideal" characteristics, which explains the high degree of variability reported in various studies of placental transfer. It appears that a classification system (based on these important physicochemical characteristics) for compounds and their ability to cross the placenta could be developed and used to guide drug therapy during pregnancy. Unfortunately, this classificatory scheme is not possible because of the tremendous interdependence of each of these physicochemical properties in determining the characteristics of the actual transfer across the placenta.

BOX 38–2 Physicochemical Factors That Influence the Transfer of Compounds Across the Human Placenta

- Degree of lipid solubility
  - Lipid soluble favored over water soluble
- Molecular weight (MW)
  - MW <100 readily crosses the placenta
  - MW 100-500 slower diffusion
  - MW 600-1000 variable placental transfer
  - MW >1000 impermeable
- pH
  - Un-ionized form under physiologic or pathologic conditions favors transfer
- Protein binding
  - Low protein binding favors transfer across the placenta

Further confusion regarding the extent to which a particular drug or compound may traverse the placenta is propagated by uncontrolled studies that compare a single maternal blood concentration to an almost simultaneous concentration obtained from cord blood. Many published experiences have attempted to quantitate drug transfer as a ratio of fetal to maternal drug concentration by using these determinations at a single point in time. Such an approach to the estimation of placental drug transfer is analogous to the severely flawed milk-to-plasma ratio, which is used to estimate drug distribution into breast milk. Unfortunately, the usefulness of such assessments is often limited and must be interpreted with extreme caution. This ratio is highly dependent on a number of important variables, including the number of maternal doses administered (i.e., first-dose compared with steady-state administration) and the time after the dose that the sample is obtained. The amniotic sac may be understood as an additional separate anatomic compartment into which a drug must be distributed. It is extremely unlikely that instantaneous distribution occurs for most of the drugs used clinically. Thus, a lag time exists for drug distribution into the amniotic sac and to the fetus, markedly shifting the concentration-time curve for the fetus to the right relative to the mother. Thus, the peak plasma concentration in the maternal circulation may occur at the trough in the fetus and conversely. It would appear that the determined absolute concentration and the interval relative to drug administration are much more important than a ratio of limited physiologic significance.

METABOLIC CAPABILITY OF THE HUMAN PLACENTA

The placenta performs many important functions that ensure homeostasis in the fetal environment. The placenta regulates the delivery of oxygen, nutrients, hormones, and other substrates from the maternal circulation to the fetus while removing metabolic end products from the fetal compartment. In addition, the human placenta is capable of synthesizing, metabolizing, and transferring a wide range of endogenous and exogenous substances. The degree to which the placenta metabolizes a drug, if at all, definitely influences the amount that is estimated to cross the placenta and the amount of active drug that reaches the fetus.

Many CYP mixed-function oxidase enzymes have been isolated from the human placenta.[49] Most of these enzymes appear to be located in the smooth endoplasmic reticulum and mitochondria of trophoblasts. Although each enzyme possesses its own substrate specificity, substantial overlap exists in the metabolizing capacity of these enzymes. It is clear that a number of these enzymes are also susceptible to modulation (i.e., induction or inhibition) by exogenous influences. For example, CYP1A activity is increased with cigarette smoking during pregnancy. In addition to mixed-function oxidase activity, the human placenta also possesses some capacity to catalyze phase II conjugation reactions. The conjugation of substances to enhance water solubility and promote excretion is a primary mechanism of in vivo drug biotransformation.

Human placental microsomal enzymes are capable of biotransforming a wide variety of chemical species. Although the number of different substrates biotransformed by enzymes located in the human placenta is large, the actual content of CYP enzymes in placental tissue is low. Attempts to quantitate the functional drug-metabolizing enzyme capacity of the human placenta have led to disparate results, but the activity appears to be much lower than that determined in the fetal or adult liver. Thus, the actual contribution of placental enzyme activity to the biotransformation of administered drugs is believed to be inconsequential and of limited clinical significance for most drugs administered maternally. Nevertheless, the differential placental metabolism of certain corticosteroids (e.g., prednisolone, in contrast to betamethasone) and the resulting poor clinical outcomes with prednisolone compared with betamethasone in enhancing fetal lung maturation suggest a significant effect of placental metabolism in certain clinical scenarios.

Drug Disposition of the Fetus

In contrast to our knowledge of drug disposition in the pregnant woman and the placenta, our understanding of drug disposition in the fetus is inadequate. Contrary to the popular belief that the fetus resides in a privileged and protected environment, it is clear that it is exposed to virtually every chemical entity to which the mother is exposed. Thus, the absorption of most drugs into the fetal circulation is both rapid and complete. Most of this absorption is believed to occur through passive nonionic diffusion down the concentration gradients between maternal and fetal blood (which oppose each other in the placental villi), where they are separated by only a single layer of cells. However, as described earlier, a number of energy-dependent placental transporters have been characterized and are responsible for drug influx and efflux.[49] In addition, the fetus may undergo continued drug exposure after its elimination because of the recirculation of amniotic fluid through the fetal gastrointestinal tract.

Once a drug is within the fetal circulation, we have little knowledge of its fate or potential activity. It will likely be distributed to the fetal organs in a manner similar to that observed after birth. However, it is not known whether there are any unusual fetal barriers to drug distribution analogous to those of the blood-brain barrier or the anterior chamber of the eye. In fact, it is not even known whether these barriers actually exist during fetal life. Additionally, a drug may have an increased affinity for a specific fetal tissue that is not the typical target tissue. For example, tetracycline has a high affinity for fetal teeth and warfarin for fetal bones.[9] Protein binding will also affect drug distribution. The fetus has lower levels of serum proteins, and the proteins that are present have a lower affinity for binding drugs. The serum protein levels increase with gestational age, but free drug levels remain high secondary to the binding affinity of fetal proteins.

Once a drug has reached various organs, it is often not known whether it has any effect at all. It is clear that both receptor number and receptor affinity change during development. Likewise, receptor-effector coupling undergoes a programmed maturation. Thus, even though a drug may interact with specific receptors, there may be no discernible pharmacologic effect because the effector mechanisms have not yet developed.

There is no question that the mean residence time for drugs in the fetus is longer than that observed in older children and adults because of the immaturity of drug clearance mechanisms. This effect is especially true for drugs that are cleared entirely by renal excretion. The ontogeny of glomerular filtration and tubular secretion has been well studied, and renal elimination is not a significant mechanism of drug excretion for the fetus. Furthermore, any drug that is renally excreted by the fetus is eliminated into the amniotic fluid, which the fetus may swallow, leading to redistribution of the drug and the need for elimination again.

In contrast, for those drugs undergoing significant hepatic metabolism, there are many unknown factors. Although most hepatic metabolic pathways are less active in the fetus than the adult, this is not universally true. Moreover, in the fetus, the adrenal gland has a significant complement of drug-metabolizing enzymes that, although active during fetal and neonatal life, disappear by 6 months of postnatal age. Thus, the true ability of the fetus to metabolize drugs is largely unknown, but it at least partially depends on the particular drug under consideration, the gestational age of the fetus, and its drug metabolism phenotype.

As noted earlier, multiple enzyme systems are involved in xenobiotic metabolism within the body. Of the phase I or oxidative enzymes, cytochrome P-450 predominates. These CYP enzymes constitute a superfamily of heme-containing monooxygenases, with a minimum of 14 CYP gene families appearing to exist in mammals. The CYP1, CYP2, and CYP3 families are the most important in human drug metabolism, with the largest number of therapeutic agents undergoing CYP metabolism by the 3A family. Although the fetuses of many species appear to possess a very poor capacity to metabolize xenobiotics, the liver of the human fetus is relatively well developed in its capacity to metabolize various compounds, and it appears to mirror those processes performed by the placenta.[2] Nevertheless, the overall functional capacity of fetal CYP activity is very low. Furthermore, the metabolic capacity of the human fetal liver is qualitatively and quantitatively very different from the activity observed in the adult liver. The human fetal liver contains many different CYP forms (Table 38-4), although they are present in fewer numbers and with less density than in the adult liver. The total amount of CYP in the fetal liver approximates 0.2 to 0.4 nmol/mg of microsomal protein, which represents about 20% to 70% of that found in the adult liver. Thus, the metabolic capacity of CYP-mediated reactions is less in the fetus than the adult.[2]

The enzyme activity that is observed in the fetus is primarily due to CYP3A7 expression, which is minimally expressed in the adult liver. CYP3A7 may serve as a detoxifying

TABLE 38–4 Expression of Cytochrome P-450 Forms in the Fetal Liver and the Adrenal Gland

enzyme and protect the fetus from steroids and retinoic acid derivatives. Other enzymes expressed also serve protective roles for the fetus, such as CYP2E1, which is involved in fetal alcohol metabolism.[9] Although our understanding of the expression of CYP forms by the fetus is growing exponentially, the extent of our understanding of their function unfortunately remains limited. Nevertheless, the available data clearly indicate that the overall functional capacity of the fetus to effectively metabolize xenobiotics is limited.[2]

Conclusions Concerning Clinical Pharmacokinetics and the Maternal-Placental-Fetal Unit

Most of the pharmacologic agents present in the maternal circulation cross the placenta and enter the fetal circulation. The myth that the placenta is a "barrier" that maintains a secure, safe environment protected from the maternal environment has long since been discounted. What is present in the maternal circulation should be considered present in the fetal circulation. The factors regulating drug transfer across the placenta (see Box 38-2) are the same as those that regulate its transfer across the biologic membranes in other parts of the body. Thus, the primary determinants of drug transfer across the placenta into the fetal compartment are the maternal steady-state drug concentration, functional capacity and specificity of transporters,[49] physicochemical drug characteristics, and integrity of the maternal and fetal circulations.

The gross physiologic changes that occur during pregnancy (see Tables 38-1 and 38-2) influence both the ultimate steady-state drug concentration achieved and the time required to achieve it. The changes that occur in maternal fluid compartment volumes, renal function (see Table 38-1), and protein binding directly influence the maternal body stores of a drug and the amount of that drug in the maternal circulation. These factors then determine the concentration gradient achieved at the maternal-placental-fetal interface and therefore the amount of the drug available for fetal transfer.

For most un-ionized, lipophilic compounds, the rate-controlling process in placental transfer is placental blood flow. Alterations in the hemodynamics of either the maternal or fetal circulation can markedly affect the placental transfer of most compounds. It seems obvious that alterations in total placental blood flow modulate the rate and extent of drug transfer from the mother to the fetus and conversely from the fetus to the mother. Numerous physiologic and therapeutic interventions can alter the hemodynamics of both circulations. For example, uterine contractions associated with labor, preeclampsia, hypertension, the removal of amniotic fluid, and the administration of oxytocic drugs decrease placental blood flow.

Once a drug crosses the placenta, it enters the umbilical vein, flowing to the fetal liver by way of the portal circulation. Portions of this blood flow enter the fetal liver, the remainder appearing to bypass this route and flowing through the ductus venosus. Any drug present in the blood that flows through the fetal liver is available for metabolism. In contrast, the compounds present in blood flowing through the ductus venosus bypass any initial metabolism, possibly allowing a greater amount of the unmetabolized portion of the compound to be distributed to its receptors in the fetus. The clinical significance and ontogeny of this phenomenon are unknown.

Given the truly rudimentary nature of our understanding of drug disposition and action in the maternal-placental-fetal unit, it seems prudent to perform focused animal experiments and controlled clinical trials before administration of any drug to a pregnant women. However, ethically, controlled trials are not often feasible in a pregnant female, and the results of animal experiments do not always correlate with the effects of human drug exposure. Unfortunately, we are often left with pharmacokinetic characteristics of the drug in question in relation to the maternal-placental-fetal unit when determining the safety and efficacy of drug therapy during pregnancy.

DRUGS AND THE FETUS

Exposure of the Fetus to Drugs

Although advances in prenatal diagnosis are now permitting physicians to consider the fetus the primary patient, it is often the passive recipient of drugs. Consequently, any effects of drugs on the fetus are usually undesirable. Such effects may vary from transient alterations of physiologic functions to irreversible structural defects. Concern has increased over the potentially harmful effects of drugs taken during pregnancy since the catastrophic teratogenic effects of thalidomide were discovered in the early 1960s.[30] This drug, thought to be harmless at the time, illustrated the totally unpredictable nature of drug toxicity in the fetus during the first trimester; thalidomide doses that induced analgesia with no demonstrable undesirable side effects in the mother produced major structural defects in the fetus.[30]

Although a number of drugs are possible teratogens in humans, at present only a few (<30) have been positively identified as such.[43] In the case of abnormalities that occur quite often in the population, physicians may not be alerted to the direct causal relationship between exposure of the fetus to the drug and the resulting adverse effect. It has been estimated that to establish that a given drug changes the naturally occurring frequency of a congenital deformity by 1%, a sequential trial involving about 35,000 patients would be required. The discovery that thalidomide caused congenital malformations was made possible because this drug was widely used, induced dramatic and rare congenital defects, and had a high probability (estimated at 20% to 35%) of producing a teratogenic effect after exposure from the third to the eighth week after conception. Unfortunately, these three criteria are rarely met when one is attempting to assess the teratogenicity of other drugs. Thus, much of the data in the biomedical literature concerning the adverse effects of drugs on the fetus is circumstantial.

MATERNAL CONSUMPTION OF DRUGS

The use of medications during pregnancy is a common occurrence, which can be appreciated by considering that in several studies, the average number of drugs prescribed during pregnancy was about four.[44,52] When self-prescribed drugs were included in these studies, the average number taken during pregnancy increased to somewhere between 8.7 and 11. Among obstetric patients, 92% to 100% took at least one physician-prescribed drug, and 65% to 80% also took self-prescribed drugs.[24] The self-prescribed use of herbal medications during pregnancy is yet another factor to consider. Their unknown effects on the fetus further underscore the importance of determining the effectiveness and tolerability of medicines ("foods") consumed during pregnancy. In addition to drug exposure, prescribed or over-the-counter, women of childbearing age must also consider environmental exposure to potential teratogens (see Chapter 12).

The physiochemical properties that allow most drugs or environmental toxins to cross cell membranes also permit their passive transport across the placenta and into the fetus. The factors involved in the placental transfer of drugs include lipid solubility and the degree of ionization, molecular weight, protein binding, affinity for specific transporters (e.g., Pgp), placental circulation, fetal circulation, placental maturation, and the metabolism of drugs.[49] Most of the drugs administered to the mother reach the fetus; the extent of fetal exposure to a drug administered to the mother depends on its physiochemical properties, the dose and duration of maternal treatment, and the rate of maternal drug elimination. If the drug is readily diffused, it can equilibrate between the maternal and fetal compartments very rapidly (Fig. 38-3). With fast transplacental equilibration and slow maternal elimination, the fetal pharmacokinetic profile mimics the maternal pattern after either a single dose or multiple doses. A drug that is polar or protein bound is diffused more slowly into the fetus. However, high concentrations of a drug may still accumulate in the fetal compartment if multiple doses are administered to the mother (see Fig. 38-3). In clinical practice, it is best assumed that the fetus and its compartment are exposed to whatever medication the mother has consumed or is consuming during pregnancy. The clinically relevant effects, if any, require careful investigation.

DRUG INGESTION BY THE FATHER

Although concern about the potential teratogenic effects of maternally ingested substances has grown in the past 30 years, the possibility that paternal drug exposure may have adverse effects on the progeny has not been of such widespread concern. In animals, there is experimental evidence of adverse effects occurring in the progeny of males that ingest certain chemicals before mating; these effects include decreased litter size and birthweight, malformations, and increased neonatal mortality. It is difficult to elucidate the mechanisms underlying this phenomenon. The drug itself may be present in semen and may cause developmental alterations after fertilization; alternatively, drug exposure may directly alter the genetic material or its packaging in spermatozoa and consequently the developmental program of the zygote.

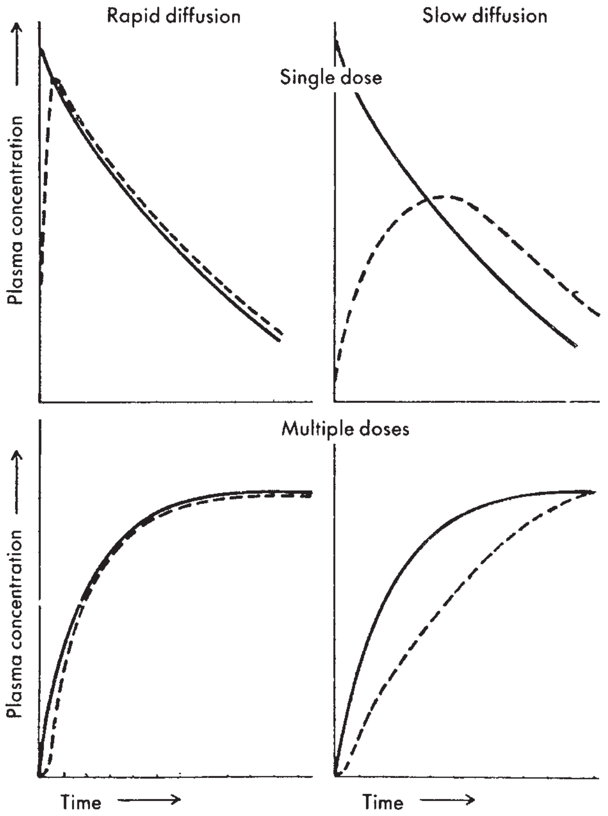

Figure 38–3. Schematic representation of maternal (*solid line*) and fetal (*dashed line*) plasma concentrations of drugs with time after single or multiple intravenous doses. Simple transplacental diffusion rates that are rapid (*left*) or slow (*right*) are hypothesized; it is assumed that the half-lives of the drugs diffusing rapidly or slowly are the same. *(From Neims AH et al: Principles of neonatal pharmacology. In Schaffer AJ et al, editors:* Diseases of the newborn, *4th ed, Philadelphia, 1977, WB Saunders.)*

In humans, a variety of paternal occupational exposures have been associated with adverse outcomes in progeny; they include exposure to wood, metals, solvents, pesticides, and hydrocarbons. Further research is needed to investigate the relationship between paternal drug ingestion and perinatal outcome in humans.

Effects of Drugs on the Fetus

The adverse effects of in utero exposure to drugs can vary from reversible effects such as transient changes in clotting time and fetal breathing movements to irreversible effects such as fetal death, intrauterine growth restriction, structural malformations, and mental retardation.[43,44,52] The specific drug, the dosage, the route of administration, the timing of treatment, and the genotype of the mother and the fetus may be critical determinants of the effect of a drug on the fetus. The disease being treated would also appear to be an important consideration. Other factors that combine to influence the outcome of drug administration include the diet and coadministration of other drugs. It is difficult to control these parameters in humans, so the incontrovertible establishment of a drug as a teratogen in humans requires the combination of extreme situations such as those previously outlined for thalidomide. Consequently, it has been necessary to rely heavily on animal studies to assess the teratogenic potential of drugs.[11]

The timing of drug exposure is frequently a critical determinant of the effect of a drug on the fetus (Fig. 38-4). The first week after fertilization is the "period of the zygote" (cleavage and gastrulation). During this time, the most common adverse effect of drugs is the termination of pregnancy, which may occur before the woman even knows that she is pregnant. Exposure of the preimplantation embryo to embryotoxic drugs may retard development, perhaps by decreasing cell numbers in the blastocyst, or it may even produce malformations. The second to the eighth week of gestation is the "period of the embryo." It is mainly during this period of organogenesis that drugs produce dramatic and catastrophic structural malformations. Other adverse effects during this phase may include fetal waste, transplacental carcinogenesis (e.g., diethylstilbestrol), and intrauterine growth restriction. From the third to the ninth month of gestation, the "period of the fetus," the differentiation of the central nervous system and the reproductive system continues. Certain drugs given during this period have been implicated as behavioral teratogens. Some drugs may cause disproportionate growth restriction (in infants whose head growth has been spared after 30 or more weeks) or may alter the differentiation of the reproductive system or external genitalia. The consideration of the irreversible adverse effects of drugs on development usually stops with birth. However, it is well known that sensory and other higher nervous system functions are not fully developed until well after birth. Thus, birth is not really a termination point but only another milestone in development.

The decision of whether to give a drug during pregnancy is difficult. If a mother is not healthy, the baby may not be healthy. If drug therapy can improve the mother's health, it seems it should also benefit the fetus. However, limited or incomplete knowledge of fetal outcomes for most drugs complicates the picture. Some of the information available on the potential adverse effects of pharmacologic classes of drugs is listed in Table 38-5, which summarizes the results of studies on the effects of in utero exposure to frequently used therapeutic agents.[7,33]

Therapeutic agents are not the only drugs of concern with regard to teratogenicity and adverse fetal effects. Chronic ethanol intake during pregnancy is associated with a readily identifiable fetal alcohol syndrome,[23,27] maternal tobacco smoking substantially reduces birthweight,[6,21] and illicit drug use can further complicate the scenario (see Chapters 12, 14, and 38, Part 2). In addition, substances in foods and drinks like caffeine must be considered. Caffeine has been found to be teratogenic in high doses in animal experiments, but some reports suggest little teratogenic danger to humans. Most authorities believe that the usual range of human exposure to caffeine from food and drink is far below any potential threshold doses that may be associated with abnormal fetal effects.[12] Nevertheless, any drug or environmental exposure during pregnancy must be considered as a potentially harmful agent to the fetus, and the risks versus benefits of its use should be weighed carefully.

FACTORS MODIFYING THE FETAL RESPONSE TO DRUGS

Genetic Background

In addition to the drug itself, the dosage, timing during gestation, and genetic background of the individual fetus and mother all play important roles in determining susceptibility to the teratogenic effects of a drug. Genetics at least partially

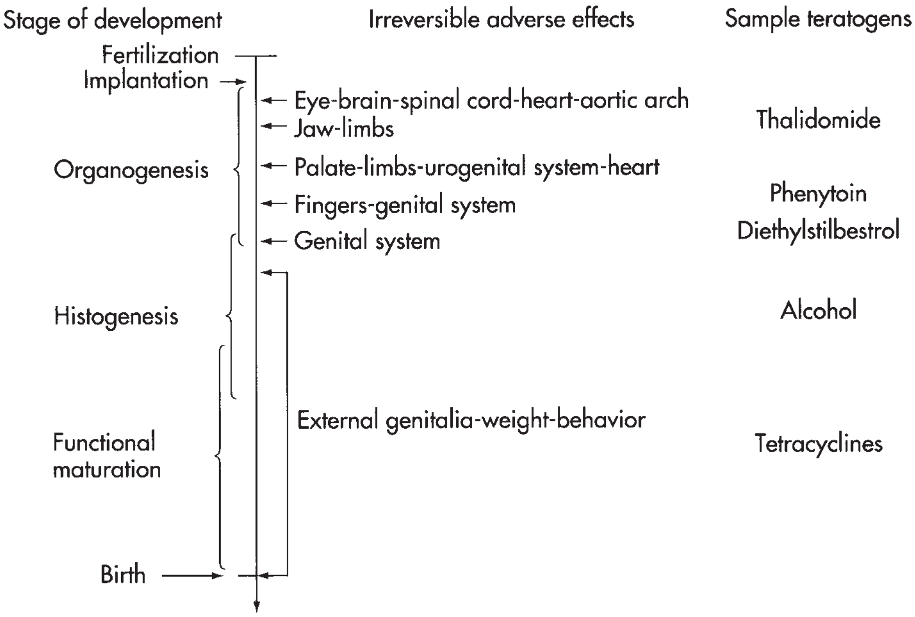

Figure 38–4. Critical periods in human embryogenesis.

TABLE 38–5 Effects on the Fetus of In Utero Exposure to Physician- or Self-Administered Therapeutic Agents

Specific Agent	Results and Recommendations
Antineoplastic Agents	
Antimetabolites, alkylating agents, antitumor antibiotics	As a group, these are the most potent teratogens known. It is difficult to delineate one agent because of frequent combined uses in addition to irradiation.
Antimetabolites (purine analogues, pyrimidine analogues, folic acid antagonists)	Potent teratogens; they are associated with skeletal defects.
Alkylating agents (busulfan, chlorambucil, cyclophosphamide, nitrogen mustard)	Some reports have described drug-related defects; others have reported cases with no drug-related defects.
Antimicrobial Agents	
Sulfonamides	Conflicting reports on teratogenicity; avoid use in third trimester because of theoretical risk for kernicterus.
Tetracyclines	Results in staining of dentition; avoid use in second and third trimesters and early childhood.
Penicillins	These appear to be safe when administered at any phase of pregnancy.
Cephalosporins	These appear to be safe when administered at any phase of pregnancy.
Aminoglycosides	Auditory nerve defects and ocular nerve damage may occur in infants after prenatal exposure.
Isoniazid	Five children with severe encephalopathies were reported after prenatal exposure; prophylactic administration of vitamin B_6 to pregnant women receiving isoniazid is often recommended.
Ethionamide, ethambutol, rifampin	No clear relationship with abnormal fetal development has been noted.
Antiparasitic agents	Quinidine has caused deafness; for others, no definite teratogenicity.
Anticonvulsant Agents	Women requiring anticonvulsant therapy should be counseled before becoming pregnant as to the nature and magnitude of risk to the fetus; overall risk for having a malformed child is about 1 in 10.
Hydantoins (phenytoin)	Typical fetal hydantoin syndrome with mild to moderate growth and mental deficiencies, limb anomalies, and dysmorphic facies (low nasal bridge, short nose, mild ocular hypertelorism) has been reported.
Barbiturates, deoxybarbiturates (Primidone, phenobarbital, secobarbital, amobarbital)	Postnatal effects are similar to those in fetal hydantoin syndrome; associated cardiovascular malformations also may occur.
Oxazolidinediones	Fetal trimethadione syndrome has been reported, with developmental delay, speech difficulty, V-shaped eyebrows, epicanthus, low-set ears, palatal anomaly, and irregular teeth.
Valproic acid	Increased neural tube defects have been found.
Carbamazepine	Associated with neural tube defects and developmental delay
Psychotropic Agents	The teratogenicity of most psychotropics is not established; caution is necessary in administering them during pregnancy; neonatal withdrawal syndrome can occur when drug is taken late in pregnancy.
Thalidomide	Teratogenic to humans when administered from the first to the eighth week of pregnancy; limb reduction anomalies.
Benzodiazepines (Diazepam, chlordiazepoxide)	Ingestion before parturition may cause hypotonia, apnea, and hypothermia.
Tricyclic antidepressants	Some evidence of increased malformations has been reported.
Monoamine oxidase inhibitors	Few data are available on humans; only phenelzine is reported as embryotoxic in rats.

Continued

TABLE 38–5 Effects on the Fetus of In Utero Exposure to Physician- or Self-Administered Therapeutic Agents—cont'd

Specific Agent	Results and Recommendations
Lithium	May induce malformations such as Ebstein anomaly. The increased risk is probably small.
Selective serotonin reuptake inhibitors (SSRIs)	Some evidence of increased cardiac malformations (mild and nonsyndromic); paroxetine is most common SSRI associated with defects.
Antinauseants, Antihistamines	No evidence of association with malformation in humans.
Non-narcotic Analgesics; Anti-inflammatory, Antipyretic Agents	Little evidence exists to associate these with malformations (see the following specific exceptions). As a group, considering their wide usage, they are not considered to be teratogenic in humans.
Salicylates	Concern exists regarding effects on platelet function that could cause hemorrhagic complications in a traumatic birth; possible intrauterine closure of patent ductus arteriosus, pulmonary hypertension.
Acetaminophen	No evidence of toxicity or association with malformations after therapeutic doses.
Narcotic Analgesics	These appear to be nonteratogenic in humans; withdrawal symptoms may occur in infants or narcotic-addicted women.
Hormones and Hormone Antagonists	
Androgens	Increased risk for masculinization or pseudohermaphroditism in humans has been reported.
Antiandrogens (Cyproterone acetate)	These are associated with abnormal sexual development in male laboratory animals; effects in humans are unknown.
Progestins (Ethisterone, norethindrone)	Depending on the treatment period during pregnancy, association with equivocal or frankly masculinized external genitalia of varying degrees has been described.
Estrogens (Diethylstilbestrol)	These are associated with vaginal adenosis and adenocarcinoma in young women exposed in utero; in exposed men, there was increased evidence of genitourinary tract disturbances but no increase in cancer incidence.
Antiestrogens (Clomiphene)	Multiple gestation has been reported.
Oral contraceptive agents	No association between first-trimester exposure and malformations.
Corticosteroids (natural and synthetic mineralocorticoids and glucocorticoids)	All are teratogens in animals, producing cleft lip and palate. Large human studies have failed to demonstrate that these agents are major teratogens.
Antithyroid agents (iodides and propylthiouracil)	These may produce neonatal goiter and tracheal obstruction; also may be associated with hypospadias, aortic atresia, and developmental retardation.
Hypoglycemic Drugs	
Tolbutamide, chlorpropamide	Neonatal hypoglycemia
Insulin	Insulin is teratogenic to mice and rabbits but not to humans.
Vitamins and Iron	These are used almost universally by pregnant women, with only rare reports of associated malformations (see the following).
Vitamin A	Hypervitaminosis A appears to be teratogenic in animals, and cases of related urinary malformations have been reported in humans.
Isotretinoin	Characteristic pattern of malformations involving craniofacial, cardiac, thymic, and central nervous system structures has been found.
Iron-containing drugs	Association with congenital malformations appears unlikely.
Diuretics	In general, these are not associated with congenital malformations.
Benzothiadiazides (thiazides)	Thrombocytopenia, altered carbohydrate metabolism, and hyperbilirubinemia have been reported in infants exposed late in gestation.

TABLE 38–5 Effects on the Fetus of In Utero Exposure to Physician- or Self-Administered Therapeutic Agents—cont'd

Specific Agent	Results and Recommendations
Cardiovascular Drugs	
Antiarrhythmics, (digitalis, glycosides)	Very few reports relate these to malformations in humans.
Antihypertensives	
Angiotensin-converting enzyme inhibitors	Hypoplasia of the skull calvaria, oligohydramnios, renal failure, death, and neonatal anemia have been reported.
Propranolol	Associations with decreased uterine blood flow and intrauterine growth restriction have been reported; bradycardia and hypoglycemia may occur in the newborn infant.
Anticoagulants	
Warfarin	Only warfarin has shown teratogenicity in humans. Exposure during the first trimester has been related to chondrodysplasia punctata and nasal hypoplasia associated with radiographic stippling of the epiphyses (Conradi disease). Exposure in the third trimester is known to cause fetal or placental hemorrhage; thus, it is recommended that patients requiring anticoagulant therapy be treated with an agent that will not cross the placenta (heparin or low-molecular weight heparin).
Cough and Cold Medicines	
Bronchodilators, centrally acting antitussive agents, decongestants, expectorants	Of these, only the iodide expectorants have been associated with adverse effects (fetal hypothyroidism and goiter).
Sympathomimetic amines (phenylephrine, phenylpropanolamine, ephedrine)	These have been associated with little risk to the developing fetus.

explains the observation that within a given exposed population, some offspring will manifest an associated malformation, whereas others do not.[32] Furthermore, under genetic control, the presence, maturity, and functional capacity of various placental transporters markedly influence fetal exposure and undoubtedly outcome.[18,49]

Experiments in mice differing at one allele have demonstrated the importance of both the maternal and fetal genotypes in determining the outcome of exposure to a toxic drug. Fraser demonstrated genetic (strain) differences in the susceptibility of inbred mice to the development of a cortisone-induced cleft palate. A study of mice deficient in glucose-6-phosphate dehydrogenase (G6PD) concluded that this enzyme was important in protecting the fetus against oxidative stress; after exposure to a teratogen, the incidence of fetal death and malformations was higher in G6PD-deficient than control mice.[37] In addition, a genetic defect in arene oxide detoxification may increase the risk that women with epilepsy who are treated with phenytoin (fetal hydantoin syndrome; see Chapter 29) could have babies with major birth defects. Thus, congenital malformations are under multifactorial control.

Drug-Drug Interactions

Individuals taking drugs rarely consume only one; rather, they use various combinations. Animal experiments have provided evidence that the administration of one drug can modify the teratogenicity of another. For example, the treatment of rats with phenobarbital increased the teratogenicity of the antitumor drug cyclophosphamide.[20] It is thought that pretreatment with phenobarbital induced maternal hepatic cytochrome P-450, increasing the activation of cyclophosphamide to mutagenic or teratogenic metabolites. It has been suggested that the teratogenic effects of anticonvulsants are more common in women on multiple anticonvulsant medications because many of these agents perturb drug-metabolizing enzymes. Moreover, one would expect drugs that modulate placental Pgp[49] to conceivably result in an increase or decrease in the exposure of the fetal compartment to selected maternal xenobiotics (see "Additional Factors that Influence Absorption," later). Unfortunately, the many negative fetal perturbations that could occur as a result of the maternal consumption of concurrent medications or herbal products are unknown.

Mechanisms of Drug Toxicity in the Fetus

Various mechanisms have been postulated for the adverse effects of drugs on the fetus. A medication may interact with a receptor or transporter, inhibit an enzyme, degrade a membrane, or chemically damage macromolecules (nucleic acids, proteins, and lipids). The consequences of such actions may include mutations, altered differentiation, inhibition of the biosynthesis of structural proteins (e.g., collagen), inhibition of tissue interactions, and altered morphogenetic movements caused by selective cell death (Fig. 38-5).

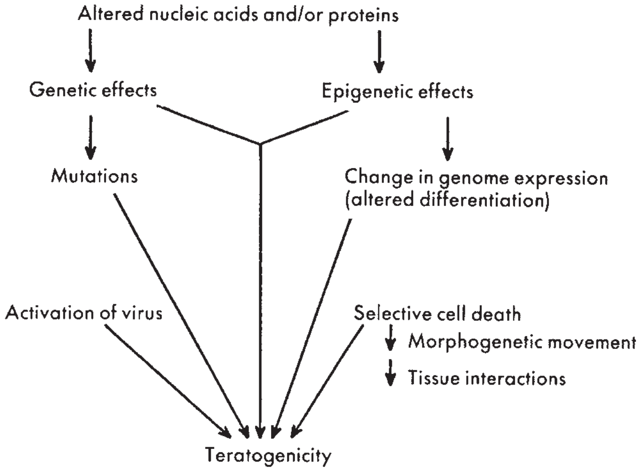

Figure 38–5. Potential mechanisms of drug-induced teratogenicity.

Some teratogens may require metabolism to an active form that is the moiety responsible for fetal harm. Early experiments with limb bud and whole embryo culture techniques suggest that at least one teratogen, cyclophosphamide, requires activation to its ultimate teratogen.[20] There is also evidence that thalidomide, phenytoin, chlorcyclizine, and diethylstilbestrol require metabolic activation to be teratogenic.[28] The ultimate teratogen may be a reactive intermediate of the drug or a reactive species of oxygen.[41] The mechanisms by which active metabolites produce their effects are thought to involve reactions with DNA (leading to covalent modification of DNA, causing base substitution or frame shift mutations), proteins (blocking crucial steps in cell metabolism), or structural lipids (promoting lipid peroxidation). We know that as a result of their instability, many active metabolites react with any available cell nucleophile. Thus, a combination of these mechanisms may be involved.

Such reactive electrophilic metabolites can be detoxified by conjugation with nucleophiles such as glutathione, which is catalyzed by the glutathione S-transferases. Animal experiments have revealed the presence of enzymes during development that may result in other deactivation processes, including hydration, glucuronidation, acetylation, and sulfation. Our understanding of the ontogeny of these processes is evolving.[25,32]

DETERMINATION OF ADVERSE DRUG EFFECTS IN THE FETUS

Human studies of the effects of drugs during pregnancy are often retrospective. Amniocentesis and ultrasonography can be used to screen for some birth defects, but pregnancy is already well advanced by the time these procedures can be used. An alternative, chorionic villus sampling, permits the detection of genetic abnormalities in the first trimester (see Chapter 8).

Epidemiologic studies can subsequently correlate a drug with a defect and thus prevent the exposure of future fetuses.[11] However, to delineate the effects of drugs, taken alone or in combination, on unidentified multiple developmental factors is difficult in humans, even in large epidemiologic studies. The facts that preclinical testing is often done in relatively small numbers of patients and that none of them are consciously pregnant underscore the importance of careful postmarketing surveillance to detect an increase in uncommon problems and specific birth defects. The international availability of teratology information services provides a new source of data for prospective epidemiologic studies with a large sample size.[17,43]

Data from animal models provide the initial information on the effects of drugs on the fetus. Such data permit the definitions of drug dosage and the timing (i.e., critical periods) of drug exposure during gestation under conditions in which the environment and genotype are controlled. This control has increased our understanding of the mechanisms of drug-induced teratogenicity. Rodents, specifically mice and rats, are frequently chosen as animal models because they are easy to breed and inexpensive and have short gestational periods. However, not all human teratogens are teratogens in different animal species. Thalidomide is an unfortunate example of a human teratogen that is not very teratogenic in rodents. Fortunately, almost every drug that has since been found to be teratogenic in humans has been shown to cause similar teratogenic effects in animals. Nevertheless, the lack of any teratogenic effects in early preclinical drug development must not be equated with the lack of possible human teratogenicity, underscoring the vital importance of postmarketing phase IV epidemiologic evaluations for teratogenic effects.[17]

Further study of the mechanisms of drug-induced teratogenicity may permit the development of antiteratogens to prevent the fetotoxic effects of the drugs essential for the mother during pregnancy. A number of such compounds (e.g., nicotinamide, ascorbate, cysteine, vitamins such as folic acid) have been studied in laboratory experiments. Some of these approaches may be useful in decreasing the incidence of adverse pregnancy outcomes in humans; there is now strong evidence that adequate periconceptional maternal folic acid supplementation is associated with a reduction in the occurrence and recurrence of neural tube defects.

New, quick, inexpensive screening tests for teratogens need to be developed. Such tests should preferably include metabolic routes of the drug similar to those in humans. Whole embryo or organ culture techniques (limb bud, palate) are being increasingly accepted as screening systems to test for teratogens in vitro. Such systems can have drug-metabolizing enzymes incorporated (in liposomes or intact human liver parenchymal cells) to activate any preteratogen such as thalidomide or cyclophosphamide. Other studies have suggested that the inhibition of tumor cell attachment may be useful in the prediction of drug teratogenicity in vitro.[19]

DRUG USE, DISPOSITION, AND METABOLISM IN THE NEWBORN INFANT

At birth, a term infant in North America receives two to three types of drugs: an ophthalmic antimicrobial agent, vitamin K, and in some institutions, an antibacterial agent for the cord. Sick infants and those with low birthweight receive an increasing number of drugs, with the constant introduction of new drugs or old drugs with new indications in the neonatal therapeutic armamentarium. Thus, the overall xenobiotic exposure of the fetus and newborn exceeds current estimates, particularly when environmental agents (e.g., lead, methyl mercury, volatile hydrocarbons), drugs of habit (e.g., caffeine, alcohol, cocaine, opiates), and maternal therapeutic agents are taken into consideration. Because many of these agents are pharmacologically active, their effects may be significant if sufficient amounts reach the fetus or newborn. Besides the usual oral or parenteral routes, unintentional portals of drug entry include the transplacental route; inadvertent, direct fetal injection; pulmonary, dermal, or conjunctival entry; and ingestion of breast milk. The lack of awareness or underestimation of the degree of drug entry through these routes and of altered drug disposition and metabolism in the perinatal period has led to well-recognized therapeutic misadventures in neonatology.[25] The prevention of toxic reactions to drugs and their rational and safe use require a thorough understanding of the various pharmacologic profiles of each drug used in the treatment of the neonate.

Figure 38-6 illustrates many of the interrelationships of the absorption, distribution, binding, biotransformation, and excretion of a drug and its concentration at the locus of action.[25] To produce its characteristic effect, a drug must be present in sufficient concentrations at its sites of action or receptor sites. The concentration of the drug at the receptor site depends not only on the amount of drug administered but also on the interrelationships listed above and shown in Figure 38-6. Those factors that have been evaluated in the newborn infant differ substantially from those in the adult and even in the young infant beyond the neonatal period.[25]

Absorption of Drugs in the Neonate

Drug absorption is the passage of a drug from its site of administration into the circulation. In a sick neonate, the intravenous route is preferred because of the ease of delivery, accuracy of dosage, possible poor peripheral perfusion, and poor gastrointestinal function. In neonates who can tolerate gastric feedings, the oral route of drug administration is the most convenient and probably the safest. The absorption of a drug or substance through the gastrointestinal system may be defined as the net movement of a drug from the gastrointestinal lumen into the systemic circulation draining this organ. This process entails the movement of drugs across the gastrointestinal epithelium, which behaves like a semipermeable lipid membrane and constitutes the main barrier to absorption. The various processes operating to induce the transepithelial membrane movement of drug molecules include simple diffusion through lipid membranes or aqueous pores of the membrane; filtration through aqueous channels or membrane pores; carrier-mediated transport, such as active transport or facilitated diffusion; and vesicular transport, such as pinocytosis. Of these, the most important is the process of simple diffusion because most drugs administered orally are absorbed through this process. This is evident from the direct proportionality between the concentration of the drug in the intestine and the amount of the drug absorbed over a wide range of concentrations. Moreover, one drug does not compete with another for transfer, indicating that the process of absorption is a simple nonsaturable one.[10,25]

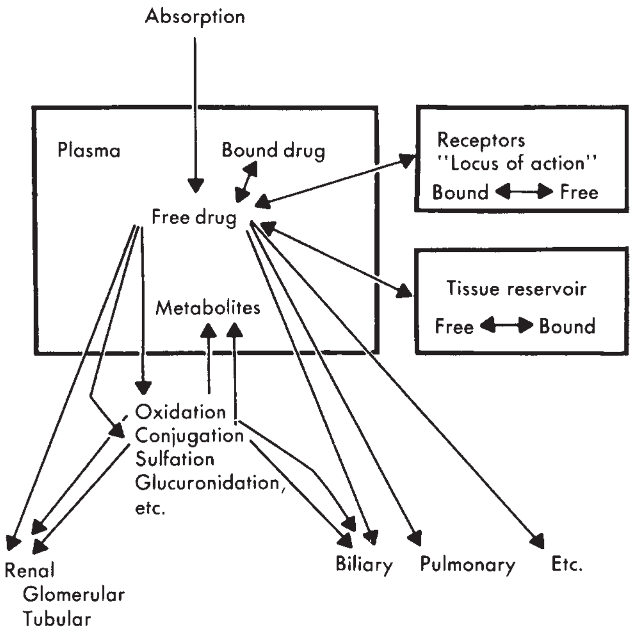

Figure 38–6. Interrelationships of absorption, distribution, biotransformation, and excretion of a drug and its concentration at the receptor site.

The rate and extent of gastrointestinal drug absorption are partly determined by the physical and chemical characteristics of the drug. Polarity, nonlipid solubility, and a large molecular size tend to decrease absorption. In contrast, nonpolarity, lipid solubility, and a small molecular size increase absorption. The degree of ionization, determined by the pK_a of the drug and the pH of the solution in which it exists, is an important determinant in drug absorption. The gastrointestinal epithelium is more permeable to the nonionized form because this portion is usually lipid soluble and favors absorption. The degree of drug ionization changes as the pH increases from the stomach through the distal portion of the gut.

Ionization also changes with the substantial changes in gastric pH observed during the neonatal period. Gastric acid production is generally low at birth, and the gastric pH is usually 6 to 8. In the first few hours of life, a burst of acid secretion occurs, decreasing the pH to values of 1 to 3. Acid secretion then returns to a low level, and the gastric pH remains near neutral for the first 10 days of life.[1] The gastric pH then tends to fall and approaches adult values by 2 years of age. These initial fluctuations in gastric acid secretion do not appear to occur in premature neonates because their gastric pH remains near 6 to 8 for the first 14 days of life.[8] Clinically, the result of any decrease in pH is the increased absorption of weak acids because they are more likely to be in the un-ionized, lipid-soluble state. Conversely, an increase in pH enhances the absorption of weak bases and limits the absorption of weak acids.

The slow gastric emptying time and intestinal motility in the newborn may also affect drug absorption. The primary site for drug absorption is the proximal bowel, which has the greatest absorptive surface area. With slower motility and emptying, it takes longer for a drug to reach this site of absorption, and the rate at which absorption can occur may be limited. Conversely, a slow transit time or slow intestinal motility may facilitate the absorption of some drugs. Further complicating the picture are the sick neonates, especially those with hypotension, whose perfusion of the gut may decrease to maintain adequate perfusion of vital organs, resulting in decreased drug absorption.

Current evidence indicates that the amount of absorption of most drugs is independent of age, although the rate of absorption of certain drugs shows a nonlinear correlation with age. Data indicate that the gastrointestinal absorption of drugs is relatively slow in the neonate and undergoes maturational changes similar to those found in drug distribution, metabolism, and disposition. Although the neonatal drug absorptive deficit may influence the achievement of an optimal pharmacologic effect, it is likely that its clinical significance is minor relative to the age-related alterations in drug distribution, metabolism, and disposition.[10,25]

ADDITIONAL FACTORS THAT INFLUENCE ABSORPTION

Two additional factors that influence the rate and extent of drug absorption after oral administration include the presence and functional capacity of Pgp and the type and extent of bacterial flora.[10,25] Pgp is normally found within the cellular membranes of the intestinal tract (duodenum, ileum, jejunum, colon), apical membrane of hepatocytes, and renal proximal tubular cells and on the luminal side of the capillary endothelial cells that comprise the blood-brain barrier and placenta. In humans, Pgp is the most prominent member of the adenosine triphosphate–binding cassette family of proteins. This protein is responsible for cellular drug efflux, translocating substances from the intracellular to the extracellular compartment. This efflux protein has an affinity for a broad range of hydrophobic substrates and effectively "pumps" xenobiotics out of cells, influencing the amount a drug that may be absorbed into the systemic circulation. Depending on the functional capacity and affinity for Pgp, the activity of this pump influences the rate at which a drug may be cleared by the liver or kidney and influences the amount of the drug that crosses the placenta or enters the central nervous system.[49] Furthermore, the activity of this important drug transporter may be modulated by the incorporation of Pgp inhibitors or inducers. It is this latter occurrence that is most likely responsible for a number of clinically important drug-drug interactions. Although only limited ontogenic data exist for Pgp, it is probable that the variability in the characteristics of intestinal absorption for many drugs is a direct result of the variability of Pgp expression within the intestinal tract as well as the presence or absence of Pgp modulators. Unfortunately, the ontogeny of Pgp in any human organ has not been described. The importance of understanding Pgp ontogeny cannot be overemphasized, considering the important role that this efflux pump plays in the absorption, distribution, and clearance of many clinically important drugs.[10,49]

Finally, the colonization of the gastrointestinal tract by bacteria is another process that influences intestinal drug absorption. Intestinal flora are involved in the metabolism of bile salts and selected drugs, as well as intestinal motility. The gut flora vary with age, type of drug delivery, type of feeding, and concurrent drug therapy. Although the actual characterization of the colonization of intestinal flora relative to age is limited, data suggest that all full-term, formula-fed, vaginally delivered infants are colonized with anaerobic bacteria by 4 to 6 days of postnatal life. By 5 to 12 months of age, an adult pattern of microbial reduction products appears to be established. Unfortunately, only very limited data on the metabolic activity of the gut flora are available, underscoring our need to better understand the ontogenic and metabolic effects of this important process.

Drug Distribution in the Neonate

Distribution of a drug into the extravascular tissues is largely influenced by body composition, which is much different in a neonate compared with an older infant or adult. Total body water is about 70% to 75% of body weight in a term infant and is an even greater percentage of body weight in preterm neonates. In comparison, an adult has a total body water percentage of 50% to 55%.[48] The extracellular water compartment of a neonate is also larger, whereas the fat content is lower. At 28 weeks' gestation, body fat is only 1% to 3% of body weight, and at term, it is 15% to 28%.[9] In addition, the fat that is found in neonates is about 50% water, compared with 25% water in an adult. The end result of these differences is a larger Vd for hydrophilic drugs, whereas lipophilic drugs may not distribute as extensively as expected. In the case of water-soluble medications, a lower peak serum concentration, higher milligram-per-kilogram doses, and delayed excretion are often observed.

Protein binding also plays an important role in neonatal drug distribution. The unbound or free concentration of a drug in plasma is considered to be the pharmacologically active fraction of the drug. For some drugs, including theophylline, phenytoin, phenobarbital, penicillin, and salicylates, the binding to plasma proteins is decreased in the newborn compared with that in the nonpregnant adult.[10] Reasons for this deficiency include decreased albumin concentrations in the neonate as well as qualitative differences in neonatal albumin. Albumin is the primary drug-binding protein in both neonates and adults, but the albumin found in neonates has less affinity for drugs compared with adult albumin. Competitive binding to albumin by many endogenous substrates, such as hormones, may also decrease protein binding. Hyperbilirubinemia may accentuate this competition because bilirubin is able to displace some drugs, such as phenytoin, from the albumin-binding site. This activity contrasts with the well-known drug-protein binding interaction with bilirubin, in which drugs such as sulfonamides or their excipients may displace bilirubin from its binding site. Regardless of cause, the decrease in protein binding observed in neonates leads to an increase in free or active drug. This outcome suggests that a more intense pharmacologic response may be obtained in the newborn infant than the adult for the same total drug concentration. Clinically, decreased protein binding in the neonate does not typically affect initial dosing, but it is important to consider this factor in the application of adult therapeutic plasma concentrations to the neonatal patient.

Drug Metabolism and Disposition in the Neonate

Many drugs are lipophilic and require conversion to more water-soluble metabolites for efficient elimination from the body. These metabolic processes are traditionally categorized as either phase I or II reactions. In a phase I reaction, a more polar compound is formed through oxidation, reduction, or hydrolysis of the parent molecule. Although they are often considered part of a detoxification process, phase I metabolites may be more pharmacologically active than the parent compound. It is the reactive product of phase I metabolism that accounts for the carcinogenic and teratogenic effects of certain xenobiotics as well as organotoxic effects (e.g., acetaminophen liver toxicity). Phase II metabolism involves conjugation with endogenous substrates such as sulfate, acetate, and glucuronic acid. Drugs may be conjugated directly or made more amenable to conjugation after the introduction of a functional group by phase I metabolism (e.g., hydroxylation). It is well recognized that the neonate is deficient in many of the enzymes responsible for phases I and II drug metabolism.[10,25] Unfortunately, these deficiencies have led to a number of adverse reactions, including the gray baby syndrome associated with chloramphenicol and cardiac arrhythmias associated with cisapride. Recent advances in our understanding of the ontogeny of the enzymes responsible for drug metabolism can explain past cases of drug toxicity in the neonate and help prevent such events in the future.

Phase I metabolism is mediated primarily by the cytochrome P-450 enzymes. These enzymes are present in several tissues throughout the body, including the intestine, lung, kidney, and adrenal glands, but are the most highly concentrated in the liver. Numerous isoforms have been identified; the primary enzymes involved in drug metabolism are listed in Table 38-6. Considerable individuality is evident with respect to substrate specificity, polymorphic expression, and susceptibility to induction and inhibition. The general pattern of development of these enzymes is illustrated in Figure 38-7. In the fetal liver, studies have shown that CYP3A7 is by far the most significant cytochrome P-450 enzyme in terms of protein expression and activity.

CYP3A7 concentrations decline during the neonatal period; in adults, the concentration is less than 20% of that for

TABLE 38–6 Characteristics of the Primary Cytochrome P-450 Enzymes Involved in Human Drug Metabolism

Enzyme	Total Cytochrome P-450 In Adult Liver (%)	Polymorphic Expression	Selected Substrates	Inhibitors	Inducers
CYP1A2	15-20	No	Caffeine, theophylline, R-warfarin	Ciprofloxacin, cimetidine, erythromycin, amiodarone, fluvoxamine	Broccoli, Brussels sprouts, omeprazole, tobacco smoke
CYP2C8/9	20-30 (includes CYP2C19)	1%-3% Caucasian PMs	Ibuprofen, phenytoin, S-warfarin	Sulfaphenazole, fluconazole, amiodarone, paroxetine, sertraline, trimethoprim	Rifampin
CYP2C19		3%-5% Caucasian PMs; 15%-20% Asian PMs	S-mephenytoin, omeprazole, diazepam, imipramine, phenobarbital, indomethacin, lansoprazole		Carbamazepine, prednisone, rifampin
CYP2D6	1-5	5%-10% Caucasian PMs; 1%-3% Asian PMs	Debrisoquine, dextromethorphan, codeine, amitriptyline, imipramine, fluoxetine, propranolol, tramadol	Quinidine, haloperidol, fluoxetine, amiodarone, cimetidine	Dexamethasone, rifampin
CYP3A4/5	30-40	No	Testosterone, ethinylestradiol, cyclosporine, clarithromycin, carbamazepine, erythromycin, indinavir, saquinavir, ritonavir, lovastatin, midazolam, quinidine, terfenadine, nifedipine, diltiazem, verapamil	Ketoconazole, itraconazole, erythromycin, cimetidine, verapamil, diltiazem, grapefruit juice, fluconazole, amiodarone, indinavir, ritonavir, clarithromycin, voriconazole	Barbiturates, carbamazepine, glucocorticoids, phenytoin, rifampin, rifabutin

PM, poor metabolizer.

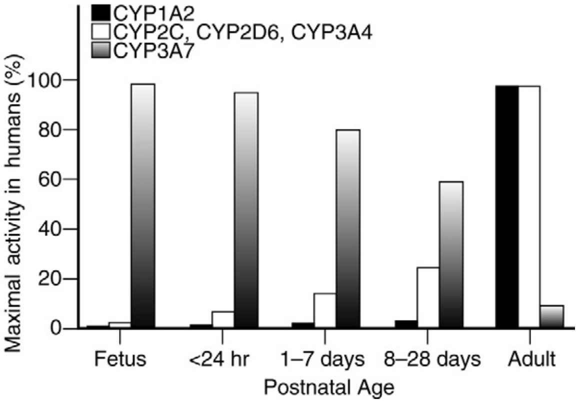

Figure 38–7. Maturational change in the activity of the cytochrome P-450 isoenzymes implicated in human drug metabolism. (See text for details.)

CYP3A4.[29,47] CYP3A4 is the most abundant CYP enzyme in adults, accounting for 30% to 40% of hepatic cytochrome P-450 and as much as 70% of the content of cytochrome P-450 in the intestine. Most other cytochrome P-450 enzymes develop rapidly in the neonatal period. Whether they are triggered by the loss of a maternal repressing factor or stimulated by transcription factors intrinsic to newborns, concentrations of CYP2D6 and CYP2E1 increase within hours of birth, followed closely by the CYP2C and CYP3A4 enzymes.[25] By 1 month of age, hepatic concentrations are about 25% to 30% of those in adults. The notable exception is CYP1A2, which develops more slowly, reaching less than 5% of adult concentrations in the first month.[25] The total content of enzymes of the cytochrome P-450 3A subfamily remains relatively constant throughout the neonatal period and into adulthood because declining concentrations of CYP3A7 are matched by increasing concentrations of CYP3A4.[29] It is generally assumed that premature babies exhibit greater impairment in drug metabolism than full-term infants; this response has been documented in several studies involving drugs metabolized by a wide range of cytochrome P-450 enzymes.[31,36] It may be due to the greater degree of immaturity of these enzymes at birth, a delay of the postnatal surge in cytochrome P-450 concentration observed in full-term babies, or a combination of these two factors.

The pharmacokinetics of many drugs in neonates is consistent with the pattern of development of the cytochrome P-450 enzymes shown in Figure 38-7. Caffeine, which is administered for the treatment of neonatal apnea, exhibits an extremely prolonged half-life of several days in neonates compared with 4 to 6 hours in adults.[31] This result is due to the delayed development of the CYP1A2 enzyme, which is responsible for the demethylation of caffeine, the primary metabolic pathway. The structurally related bronchodilator theophylline also exhibits reduced clearance and a prolonged half-life in neonates. However, the effect is not as dramatic as that observed with caffeine because theophylline is partially oxidized by other cytochrome P-450 enzymes, such as CYP2E1 in addition to CYP1A2. For drugs metabolized primarily by CYP2D6 or CYP2C, it seems reasonable to expect drug clearance to be low at birth but increase rapidly during the first month of life. Data on tolbutamide and phenytoin, which are substrates for CYP2C9, support this view. The half-life of tolbutamide was found to decrease from 46 hours to 6 hours within the first 2 days after birth in a neonate exposed to the drug by placental transfer from the mother. The clearance of drugs metabolized by CYP3A4 may be reduced less in neonates than substrates for other cytochrome P-450 enzymes if CYP3A7 is capable of contributing to the metabolic process. CYP3A4 and CYP3A7 show more than 85% amino acid sequence homology and have partially overlapping affinities for both endogenous and exogenous substrates.[39] CYP3A7 appears to play an important role in the metabolism of steroids by the fetus and is 10- to 20-fold more active than CYP3A4 in catalyzing the 16α-hydroxylation of dehydroepiandrosterone. In addition, the ratio of 6β-hydroxycortisol to cortisol in urine declines in a parallel manner with the decrease in CYP3A7 concentration in neonates, suggesting that CYP3A7 is involved in this reaction. The catalytic activity of CYP3A4 toward drugs such as midazolam, carbamazepine, and nifedipine is greater than that of CYP3A7, whereas the latter appears relatively active in metabolizing erythromycin.[39] However, even if catalytic activity is low, CYP3A7 may contribute to the overall clearance of a drug at birth owing to the high concentrations present. This activity may account for the observation that the elimination of CYP3A substrates such as carbamazepine[46] and the reverse transcriptase inhibitor nevirapine[35] during the first week of life is relatively similar to that observed in adults.

The metabolism of phase II drugs is mediated by a number of different enzymes, the most important of which are *N*-acetyltransferase (acetylation), sulfotransferase (sulfation), and uridine 5′-diphosphate glucuronosyltransferase (UGT) (glucuronidation). Acetylation and glucuronidation are not completely developed at birth, whereas sulfation appears to be reasonably well developed relative to other pathways of drug metabolism. Acetylation activity is polymorphically expressed in adults, with 10% to 20% of Asians and 40% to 60% of whites and African Americans being slow acetylators. Delayed development in neonates is suggested by some studies indicating that a much higher percentage (>75%) of newborns and children younger than 2 years of age are phenotypically slow acetylators of caffeine and isoniazid compared with adults.[40] Glucuronidation is an important route of metabolism for many drugs (acetaminophen, morphine, zidovudine) as well as endogenous compounds such as bilirubin.[16] Although UGT activity is generally presumed to be immature at birth, establishing a clear pattern for its development is complicated by the existence of numerous isoforms of the enzyme with broad and overlapping substrate specificity. UGT1A1, which is involved in the glucuronidation of bilirubin, is virtually absent in the fetus and develops slowly over several months after birth. A somewhat similar pattern of development exists for UGT1A6, which is responsible for the glucuronidation of acetaminophen. UGT2B7 is expressed to a greater extent in the fetus and neonate (10% to 20% of adult values) and catalyzes the formation of morphine-3-glucuronide and morphine-6-glucuronide.[16] However, morphine clearance in neonates remains well below that of older children. The UGT isoform involved in the metabolism of substrates such as zidovudine and chloramphenicol has not been clearly identified. Chloramphenicol is of particular interest because impaired glucuronidation is the primary cause of gray baby syndrome, which is associated with the use of this drug. Similar to observations with drugs metabolized by cytochrome P-450, glucuronidation in premature infants is impaired to a greater extent than it is in full-term infants.[34,42] Increased sulfation partially compensates for the reduced glucuronidation of some medications, such as acetaminophen, in neonates. The proportion of a dose of acetaminophen excreted as a sulfate conjugate is higher in neonates than older children or adults.

Conclusions based on studies of drug metabolism in the neonate must be interpreted with caution because of the small numbers of subjects in many investigations and the potentially confounding effects of genetics and disease states on metabolism because access to healthy babies during the first month of life is limited. Nevertheless, the available data suggest the following tentative conclusions:

1. The rate of drug metabolism is generally low at birth in full-term babies and even lower in premature infants regardless of the specific route of metabolism. Decreased clearance and a prolonged drug half-life require drug administration with longer dosing intervals.
2. Many of the enzymes responsible for metabolism exhibit significant development during the first month of life. Dosing regimens appropriate during the first few days of postnatal life may not be appropriate 3 to 4 weeks after birth because dose requirements may increase and dosing intervals decrease.
3. The development of individual drug-metabolizing enzymes varies widely among neonates and may be delayed in premature infants. Predicting clearance is difficult, and dosing regimens must be individualized for patients based on the careful observation of the patient's response and tolerance; monitoring of plasma drug concentrations may be useful for selected drugs.

Renal Excretion of Drugs

The kidneys are the most important organs for drug elimination for most agents. In the newborn, the most frequently used drugs, such as antimicrobial agents and caffeine in the premature neonate, are excreted by way of the kidney. Renal elimination of these drugs reflects and depends on neonatal renal function, which is characterized by a low glomerular filtration rate, low effective renal blood flow, and low tubular function compared with that in the adult (see Chapter 51). The neonatal glomerular filtration rate is about 30% of the adult value and is greatly influenced by gestational age at birth. A term neonate has a glomerular filtration rate of 2 to 4 mL per minute per 1.73 m^2, whereas the glomerular filtration rate at less than 34 weeks of gestation is about 0.6 to 0.8 mL per minute per 1.73 m^2.[25] The ontogeny of renal function is addressed in more detail in Chapter 51. The most rapid changes in renal function occur during the first week of life, and these events are reflected in the plasma disappearance rates of aminoglycosides, which are eliminated mainly by glomerular filtration. These age-related (gestational and postnatal) changes have been considered in the dosage regimen recommendations for drugs and other antibiotics used in the treatment of infants.[25]

Effective renal blood flow may influence the rate at which drugs are presented to and eliminated by the kidneys. Effective renal blood flow, as measured by para-aminohippurate (PAH) clearance, is substantially lower in infants than adults, even when PAH extraction values are correlated (i.e., PAH extraction is 60% in infants, compared with greater than 92% in adults). Available data suggest that there is low effective renal blood flow during the first 2 days of life (34 to 99 mL per minute per 1.73 m^2), which increases to 54 to 166 mL per minute per 1.73 m^2 by 14 to 21 days and further increases to adult values of about 600 mL per minute per 1.73 m^2 by age 1 to 2 years. These data are probably not applicable to premature infants with very low birthweight, particularly those who weigh less than 750 g at birth. It is assumed, pending definitive data, that the glomerular filtration rate and renal blood flow in these micronates are substantially lower than those in bigger, premature infants, such as those who weigh more than 1000 g at birth. Nevertheless, renal function in these patients is highly variable and reflected in the highly variable body clearance of a number of commonly administered drugs. This underscores the need for the rigorous monitoring of drug efficacy and patient tolerability in the often unpredictable micronates.

The pharmacokinetic behavior of drugs eliminated through the neonatal kidneys exhibits characteristics similar to those underlying hepatic biotransformation. For instance, the half-lives of many antimicrobials, such as ampicillin (Fig. 38-8),

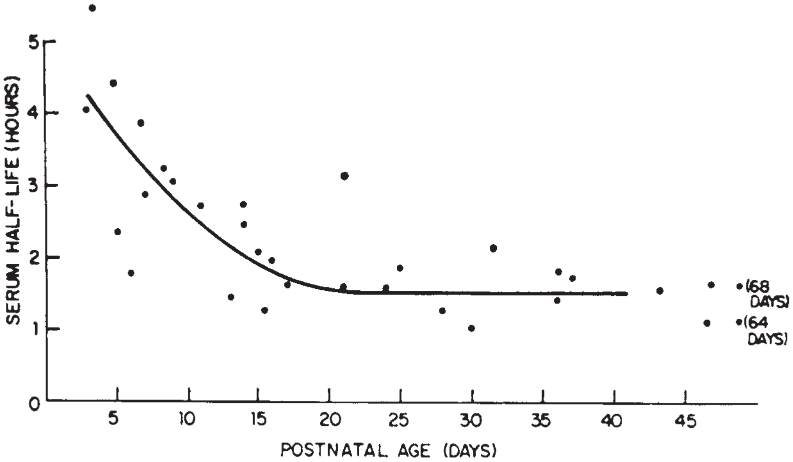

Figure 38–8. Postnatal changes in the serum half-life of ampicillin. *(From Axline SG et al: Clinical pharmacology of antimicrobials in premature infants. II. Ampicillin, methicillin, oxacillin, neomycin, and colistin,* Pediatrics *39:97, 1967. © American Academy of Pediatrics, 1967.)*

show marked interindividual variability at birth, which narrows somewhat with advancing age. The plasma half-life also shortens progressively after birth, achieving adult rates of elimination within 1 month. The drug-dependent variability in the elimination process partially reflects the major renal mechanism of drug excretion. Those drugs that undergo substantial elimination by glomerular filtration (e.g., aminoglycosides) may be excreted more rapidly than those requiring substantial tubular excretion (e.g., penicillins). These differences may reflect neonatal glomerular preponderance. Studies of the pharmacokinetics of ceftazidime and famotidine have shown direct correlations between plasma drug clearance and the maturational changes in renal function.[25]

As with hepatic metabolism, the renal excretion of certain drugs may be as efficient as that in adults. For example, colistin, an antibiotic, is eliminated by neonates at rates similar to those in adults. However, as a rule, drug excretion by way of the neonatal kidneys is deficient relative to that in the adult. Pathophysiologic insults further compromise the inherent deficiency in drug elimination, complicating individual drug dosage regimens. Hypoxemia decreases the already slow glomerular and tubular functions in neonates, leading to the slower renal excretion of drugs, as shown with amikacin. A linear relationship between oxygen tension and hepatic oxidation has been reported, so drugs that require hepatic biotransformation or renal excretion may be excreted much more slowly when hypoxemia is present. Moreover, very small infants, who receive the most drugs in the neonatal population, exhibit the worst functional deficiency in drug elimination. Unfortunately, if drug doses are not adjusted appropriately, accumulation and toxicity may ensue. The determination of the plasma concentrations of drugs, coupled with appropriate caution and clinical awareness, helps ensure optimal and safe drug therapy in the neonate.

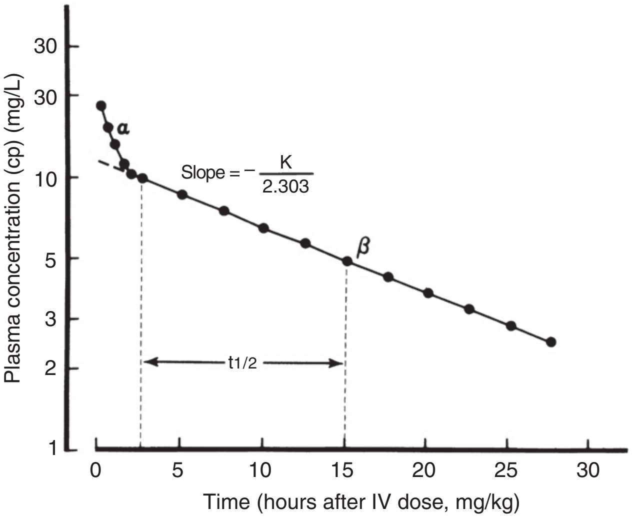

Figure 38–9. Representative plasma disappearance curve of a drug given intravenously and plotted semilogarithmically as a function of time. A fast distribution phase (α) is followed by a slower elimination phase (β). IV, intravenous.

Pharmacokinetic Considerations, Dosage Guidelines, and Therapeutic Monitoring in Neonatal Drug Therapy

See Appendix A.

Knowledge of the pharmacokinetic profile of a drug allows the manipulation of the dosage to achieve and maintain a given plasma concentration. A typical plasma disappearance curve for a drug administered in the newborn period is shown in Figure 38-9. In this example, the log of the plasma concentration decreases linearly as a function of time, with a brief but fast distribution (alpha [α]) phase and a slower elimination (beta [β]) phase. This process exemplifies a nonsignificant two-compartment model and first-order kinetics; that is, after the distribution phase, the plasma concentration reflects or is proportional to the concentration of the drug in other parts of the body, and a certain fraction (not amount) of the drug remaining in the body is eliminated with time. This compartment model is applicable to a wide variety of drugs used in the neonatal period. For newborn infants, in whom the elimination phase is extremely prolonged relative to the distribution phase, the relative contribution of the distribution phase to overall elimination and dosage computations may not be significant. Thus, the entire body may behave kinetically as though it were a single compartment (e.g., the one-compartment model or the nonsignificant two-compartment model). However, there are agents (e.g., diazepam, digoxin) used in neonates that fit a significant two-compartment model, in which the distribution phase is prolonged and must be accounted for in pharmacokinetic evaluations. There are also drugs (e.g., ethanol, phenytoin) that exhibit saturation kinetics instead of first-order kinetics; that is, a certain amount (not fraction) of the drug is eliminated per unit of time. The computations and dosage adjustments for drugs that have saturation kinetics can be significantly more complex than those required when first-order kinetics is involved.

Other important aspects of a drug's kinetic profile to consider are volume of distribution (Vd) and its impact on loading dose, and half-life in relation to maintenance dosing. The administration of a loading dose (in milligrams per kilogram) to quickly achieve a given plasma drug concentration is appropriate for drugs with a long half-life whose effect is required immediately. For many drugs used in neonates, loading doses are generally greater than those for older children or adult subjects. This requirement of a larger loading dose in neonates reflects the differences in the amounts and distribution of body water between the neonate and older infants or adults, as previously described. With regard to maintenance dosing in neonates, the prolonged half-life exhibited by many drugs warrants longer intervals to prevent toxic effects or overdosage. The rapid postnatal changes in drug elimination require the adjustment of maintenance dosage rates (in milligrams per kilogram per day) with advancing postnatal age; this adjustment may also be a function of the drug used. Monitoring drug concentrations is extremely useful if the desired pharmacologic effect is not attained or if adverse reactions occur and a clear relationship has been defined between the drug's effect and the pharmacodynamic response (see later). Moreover, therapeutic drug monitoring seems prudent, especially for those drugs with a narrow therapeutic index used during a period in which there is a rapid change in drug elimination.

In the clinical setting, the therapeutic drug monitoring of anticonvulsants (phenytoin, phenobarbital, carbamazepine), antimicrobials (gentamicin, tobramycin, chloramphenicol, vancomycin), cardiac glycosides (digoxin), and methylxanthines (caffeine, theophylline) is often useful in individualizing drug therapy.[10,25] Rapid microassay techniques such as the enzyme multiplied immunoassay and high-pressure liquid chromatography require only small volumes of blood samples and are well suited for neonates. Therapeutic drug monitoring to verify the appropriateness of the drug dosing schedule is useful when (1) dose adjustments are contemplated, (2) there is the lack of a desired therapeutic effect, (3) there are adverse or toxic effects, and (4) factors modifying drug metabolism and elimination are present, such as abnormal renal and hepatic function. Because most of the drugs used in neonates exhibit first-order kinetics, the change in dose is proportional to the change in plasma drug concentration at a steady state. Thus, a plasma phenobarbital concentration of 10 mg/L at a dose of 5 mg/kg per day would be expected to increase 100% to 20 mg/L if the dose were increased 100% to 10 mg/kg per day. Conversely, a plasma phenobarbital concentration of 10 mg/L would decrease to 5 mg/L if the phenobarbital dose were decreased 50% to 2.5 mg/kg per day. These predictions are expected to occur at a steady state, in which the fraction of the drug dose eliminated from the body is usually held constant with the amount absorbed.

For many drugs used in the neonatal intensive care unit, published definitions exist for "target" plasma drug concentrations, such as aminoglycosides, vancomycin, and anticonvulsants. However, the sensitivity of these purported concentrations for many drugs administered to neonates, particularly antimicrobial drugs, are highly questionable. Critical analysis of the literature published during the past three decades attempting to correlate plasma antibiotic concentrations fails to substantiate a sensitive, direct relationship between plasma aminoglycosides or vancomycin levels and adverse effects. Nevertheless, these data do demonstrate that if the antibiotic plasma concentration remains within the purported target range, clinical efficacy is usually achieved. Thus, the dosing of those drugs in sick neonates should be focused on the use of defined, age-appropriate dose regimens that rely on this body of "population-based" evidence. Plasma drug concentrations should be obtained in those patients who are not responding to therapy as expected or demonstrate adverse effects, or whose excretory organ function markedly changes during therapy.

Roles of Fetal Maturity and Advancing Postnatal Age on Neonatal Drug Dose and Dose Interval

Infants with very low (≤500 to 750 g) to low (751 to 1000 g) birthweight are showing increasing numbers in many neonatal intensive care units. This phenomenon is due to several factors, including attempts to decrease the rates of perinatal death caused by fetal distress, fetal growth restriction, premature rupture of membranes, or simply the inability to stop labor by existing tocolytic measures. The major organs for drug metabolism and excretion in these very small, premature neonates—namely the liver and kidneys—are substantially immature; therefore, the plasma clearance of drugs is exceptionally slow or diminished. This fact indicates that the total drug dose per day must be decreased and the intervals between drug doses must be much longer than those in term newborns or premature neonates with a greater degree of maturation (i.e., greater than 32 weeks of gestation). Drug doses, particularly for those agents excreted by the kidneys, are dynamically changing as functions of gestational and postnatal ages. These requirements are exemplified by two agents commonly used in the neonatal nursery—gentamicin and vancomycin. In general, the total daily dose of the drug is directly related to postconceptional age. The lower the fetal or postconceptional age, the smaller the total daily drug dose. Moreover, fetal maturity is inversely related to dose interval. Thus, the younger the gestational age, the longer the dose interval. These dose adjustments reflect the relatively deficient drug elimination of the very small, premature infants discussed previously.

DRUGS AND LACTATION

Investigations of drugs and other compounds in breast milk have been hampered by the very small numbers of lactating women studied and the insensitivity of drug assay methods. Much of the early literature concerns isolated case reports and a small selection of drugs.[13] With today's higher incidence of breastfeeding, there are more situations in which lactating women are exposed to various medications, and an increasing number of useful studies of drugs in breast milk can be expected. There are currently up to 80% of Canadian and American women who breastfeed their infants; unfortunately, as many as 50% discontinue breastfeeding by 3 to 4 months after delivery. In addition to pharmaceuticals, environmental pollutants and nontherapeutic or "social" chemicals find their way into breast milk. Public awareness of these problems is high, and the clinician is often called on for counseling.

Passage of Exogenous Compounds from Maternal Blood to Milk

For the most part, drugs enter breast milk by passive diffusion. The presence and concentration of compounds in breast milk depend on a number of important factors, including the drug's molecular weight, degree of ionization, protein binding in blood, lipid solubility, and specific uptake by mammary tissue, as well as the amount and composition of the milk. The constituents of breast milk vary relative to the postpartum period and could influence drug distribution and accumulation within breast milk, depending on the drug's physiochemical characteristics.[13]

Small compounds with molecular weights of less than about 200 daltons appear freely in breast milk and are presumed to have passed through pores in the mammary alveolar cell. Large compounds such as insulin or heparin, or those that are protein bound, do not enter the milk. Intermediate-sized compounds must penetrate the lipoprotein cell membrane by diffusion or active transport. Drugs or other chemicals that are very lipid soluble readily cross the alveolar cell, and because breast milk contains a considerable amount of lipid, these compounds are trapped in the milk. In general, drugs that are not ionized at blood pH traverse the alveolar cell membrane with greater ease than highly ionized compounds. Therefore, weak acids, which are more likely to be ionized at the plasma pH of 7.4, are less likely to enter breast milk, whereas weak bases pass into breast milk more readily. Because breast milk pH is 7 or slightly less, once a weak base crosses into breast milk, it may become more ionized and trapped.

A number of important variables specific for the type of drug, age, and time after delivery or disease influence a drug's ability to penetrate into breast milk. The interrelationships between these and other variables yet to be identified are complex, making it very difficult to predict the actual amount of drug distribution into the milk. Although many investigators and clinicians have attempted to collapse the many important characteristics into one simple surrogate marker of drug penetration into breast milk, that is, the ratio of milk to plasma protein (M/P ratio), this parameter is overly simplistic and often misrepresents the true nature of drug distribution into breast milk. The M/P ratio is defined as the ratio of the drug concentration in breast milk to the drug concentration in maternal plasma at a simultaneous point in time after maternal drug administration. Thus, the M/P ratio is based on the erroneous assumptions that the drug concentrations in maternal blood and milk are constant and in equilibrium at the time of sampling and that the drug's distribution characteristics in these two matrices are parallel. Although the M/P ratio is often quoted, it cannot account for many of the interdependent variables important for systemic drug distribution. Although many investigators have realized the limitations of the M/P ratio for decades and alternative mathematical models of varying complexity have been developed as M/P replacements, all of them have yet to be validated, and the complexity of most limits their clinical usefulness. Based on these real and severe limitations, the M/P ratio should be used with caution, if at all, as a means of quantitating drug distribution in breast milk and infant exposure. Alternatively, the M/P ratio may be used as a simplified qualitative measure of infant exposure combined with the knowledge of a drug's physiochemical and pharmacokinetic characteristics and appropriate infant monitoring of the drug's primary and secondary effects.[5,13]

Delivery of Compounds to and Disposition of the Infant

The concentration of the drug in milk and the total volume of milk consumed by the infant in a known period determine the dosage delivered. Because the daily volume intake of breast milk is exceedingly variable and impractical to measure routinely, one could assume a high average daily consumption of milk to be about 1 L at or beyond term. To produce an effect, the drug in the milk must either act locally in the gut or be absorbed. As a rule, if a drug is not orally bioavailable (vancomycin), the infant will not absorb the medication, even if it is present in breast milk. However, it is possible that the bowel of a very young infant may permit the absorption of large molecules that are normally excluded. Another potential barrier to absorption is found in milk proteins that bind certain drugs and impede absorption. Unfortunately, for most drugs, the extent of oral absorption by the breast-fed infant is unknown. If absorption does occur, the infant's handling of the medication is often unclear and changes with postnatal age. Ultimately, close monitoring of the infant for adverse effects associated with the maternal drug therapy is required.

Compounds in Breast Milk

ANTICOAGULANTS

Heparin has a molecular weight of about 20,000 daltons and does not enter breast milk. Newer synthetic heparin has a much lower molecular weight (3000 daltons) but is still too large for passage into breast milk. Additionally, heparins are unstable in gastric contents, so any small amount that might pass into breast milk would be quickly degraded. These drugs are safe for use during breastfeeding. Oral anticoagulants of the indanedione group, as well as bishydroxycoumarin and ethyl biscoumacetate, are found in milk and have been associated with infant coagulopathies, therefore warfarin must be considered the drug of choice. Warfarin is a weak acid with a high degree of protein binding, and it is undetectable in breast milk.

ANTI-INFLAMMATORY AND ANALGESIC DRUGS

Ibuprofen is considered compatible with breast feeding and is not transferred into breast milk in significant amounts. In a case report, only 0.0008% (based on milligrams per kilograms) of the maternal dose reached the nursing infant.[51] Although detailed studies do not exist, acetaminophen also appears to be safe.

ANTIMICROBIAL DRUGS

Fortunately, most antimicrobial agents in breast milk appear to be safe for nursing infants.[13] Selected antibiotics, particularly those with broad antimicrobial spectra, may change the infant's intestinal flora and cause diarrhea and thrush; theoretically, they could also incite hypersensitivity. The cephalosporins appear to be secreted in insignificant amounts in breast milk. The passage of the various sulfonamide derivatives is influenced by their differing degrees of ionization and protein binding; all have the potential to displace bilirubin from albumin. The ingestion of sulfasalazine leads to the appearance of the metabolite sulfapyridine in breast milk; it has been estimated that the infant of a mother using this drug on a long-term basis will receive about 0.3% of the maternal dose per day. The amounts present in breast milk, combined with the actual bioavailable dose to the infant, suggest that maternal sulfonamide administration is acceptable during breastfeeding, except in neonates at high risk for hyperbilirubinemia, including extremely premature neonates or those with very low birthweight. Erythromycin, clarithromycin, and azithromycin are present in milk in a higher concentration than that in maternal plasma. This accumulation of the macrolides and azalide in breast milk reflects the tremendous cellular tissue penetration characteristics of these drugs. Nevertheless, the actual amount an infant would receive per day from breastfeeding would appear to be minimal, particularly when one considers the poor bioavailability characteristics of these agents. The tetracyclines in breast milk purportedly have the potential to cause dental staining, and many sources have suggested that women taking tetracyclines avoid breastfeeding. Closer examination of these suggestions against breast feeding during tetracycline therapy appear to be based on theoretical grounds rather than any supporting evidence. Moreover, the bioavailability of tetracyclines under the conditions of breastfeeding suggests that the maternal administration of tetracycline and its analogues is safe and without complications in infants.[13] Similarly, most authors recommend that chloramphenicol not be taken by lactating women, even though the drug levels in milk would not produce a dose anywhere near that associated with gray baby syndrome. The aminoglycosides are poorly absorbed from the infant's gastrointestinal tract. Isoniazid and para-aminosalicylate have not been associated with ill effects in nursing infants. Metronidazole therapy in the usual doses is not contraindicated for breastfeeding women.

The data outlined previously and elsewhere[13] demonstrate the overall safety of most maternally administered antibiotics to the breast-fed infant, and only in rare instances should mothers requiring antibiotic therapy be recommended to discontinue breast feeding their infant.

DRUGS AFFECTING THE CARDIOVASCULAR SYSTEM

The amount of digoxin present in milk depends on the maternal dose; infants whose mothers received 0.25 mg/day did not ingest enough digoxin in milk to have detectable blood levels. Diuretics in general appear to be harmless, although if a nursing woman were to become dehydrated because of diuretic use, lactation would be greatly depressed. The effects of diuretics on milk composition are not clear. Spironolactone and its less active metabolite are secreted in breast milk, and an estimated 0.2% of the mother's daily dose is received by the infant. Chlorthalidone and propranolol appear in small amounts in breast milk and seem safe. In contrast, the water-soluble, renally excreted β-adrenergic receptor antagonists atenolol and acebutolol should be avoided during periods of breastfeeding because these agents have been shown to induce β-receptor blockade in breast-fed infants.[5] Quinidine is secreted in breast milk at a concentration that is about 60% of that found in maternal blood, but no ill effects have been observed.

DRUGS AFFECTING THE CENTRAL NERVOUS SYSTEM

Antidepressants are commonly administered before conception and during postpartum. Of the older tricyclic antidepressants, most appear safe during lactation, with minimal to no infant effects. However, one of them, doxepin, should be avoided during breast feeding because maternal administration has been associated with infant sedation and unresponsiveness. Among the newer class of antidepressants, the selective serotonin reuptake inhibitors, which are the preferred agents in the treatment of most patients with depression, the greatest number of case reports describing effects in infants involves fluoxetine. This finding is not unexpected considering the pharmacologic activity and lipid solubility characteristics of fluoxetine and its primary active metabolite norfluoxetine and the slow body clearance of both compounds. Infant manifestations of fluoxetine exposure during breast feeding have usually involved gastrointestinal complaints, agitation, and lethargy, resulting in poor feeding.[5] These effects reverse in maternal when fluoxetine is discontinued, but complete reversal may take up to 5 to 7 days because of the very slow neonatal elimination of accumulated norfluoxetine. For this reason, sertraline or paroxetine would appear to be preferable for use in breastfeeding mothers because both are cleared from the body at intermediate rates compared with fluoxetine, and metabolites appear to have limited, if any, contribution to the drug's overall pharmacologic and side-effect profiles.

Anticonvulsants are also a common concern for breastfeeding mothers. Phenytoin is found in breast milk in concentrations about one fifth of those in maternal blood. Primidone and ethosuximide both achieve breast milk levels near that of maternal blood, although significant symptoms in infants have not been noted. The concentration of barbiturates in breast milk depends on their different degrees of ionization and lipid solubility, but in anticonvulsant doses, they appear to be safe.[38] However, phenobarbital is metabolized much more slowly in neonates than adults; it is possible that the drug may accumulate in the breast-fed infants of phenobarbital-treated mothers. These infants should be monitored for lethargy and poor weight gain.[3] Diazepam is converted in the body to the active metabolite desmethyldiazepam, and both are excreted in breast milk. Both of these compounds have prolonged half-lives in infants, and the long-term use of diazepam by nursing women has been associated with lethargy and weight loss in their babies. Chlordiazepoxide in breast milk has been linked to depression in nursing infants. Meprobamate should probably be avoided because the drug achieves breast milk concentrations several times greater than those in maternal plasma.

Lithium has been contraindicated during lactation because of a few case reports that described significant cardiovascular and central nervous system signs in two infants. It would appear from a closer evaluation of these cases that transplacental exposure cannot be ruled out, and maternal drug interaction may have predisposed these infants to a level of lithium toxicity beyond what would have occurred from breastfeeding alone. As a result, breast-feeding mothers who require lithium therapy should be permitted to continue to breastfeed, with close infant monitoring that could include the measurement of blood lithium concentrations in the infant 1 to 2 weeks after initiating breast feeding.

DRUGS AFFECTING THE ENDOCRINE SYSTEM

A common problem confronting health care providers is the maternal concern over the use of oral contraceptives during lactation. Little is known about the effects of long-term exposure to small doses of these compounds in breast milk. Contraceptives with a high concentration of estrogen and progestin depress lactation, especially if they are begun soon after parturition. If their use is imperative, it is best to start treatment about 4 weeks after delivery, ensuring that lactation is already well established, and to use the lowest dosage possible. The infants should be followed with care because there have been reports of gynecomastia and changes in the vaginal epithelium. A study of delayed effects in exposed infants is urgently needed. However, contemporary oral contraceptives contain low maternal hormone doses, and many are progestin-only products. The oral contraceptives in current clinical use are not contraindicated for mothers who are breastfeeding, and those that are progestin-only products should be considered the oral contraceptive preparations of choice during breast feeding.[5]

Drugs affecting thyroid function are also commonly encountered in postpartum women. Drugs of the thiouracil family, such as methimazole, carbimazole, and iodides, are contraindicated during breast feeding; they achieve a high breast milk concentration and can suppress the infant's thyroid function.[3] Revision of this dogma has been suggested, and propylthiouracil may be given to nursing mothers, provided that the infant's thyroid function is monitored. Thyroxine and other thyroid hormone preparations appear to be safe; endogenous thyroid hormone, which is naturally secreted in breast milk, may mask congenital cretinism during breast feeding.[3]

The long-term effects of exogenous glucocorticoids and their derivatives in breast milk are not known. Women receiving prednisone and prednisolone excrete very small amounts of these compounds in breast milk.

OTHER DRUGS

Cimetidine, a histamine H_2-receptor antagonist, has been reported in breast milk at concentrations 3 to 12 times greater than those in maternal blood; this drug may be actively transported into breast milk. Because cimetidine and ranitidine are known to be safe and effective when used for therapy in infants, they are not contraindicated during lactation. Similarly, proton pump inhibitors (e.g., omeprazole, lansoprazole) are also used in neonates and infants and should be safe for maternal use during breastfeeding because of the expected low infant exposure to these drugs.

Maternal theophylline ingestion has been associated with infant irritability. Extracts of ergot have been responsible for toxic reactions in nursing infants and should be avoided. The use of isotopes for diagnosis or therapy should be avoided during lactation. An acceptable level of an isotope in breast milk is not known. It has been suggested that women not nurse for 10 days after exposure to ^{131}I, 3 days after exposure to ^{99m}Tc, and 2 weeks after exposure to ^{67}Ga. If radiopharmaceuticals are required during lactation, breast feeding should be avoided while the radioactive agent is present in breast milk. In uncertain cases, consultation should be obtained from a specialist in nuclear medicine.

Narcotics

Heroin, methadone, morphine, and other opiate derivatives have been found in breast milk and may be responsible for both addiction and withdrawal symptoms in the nursing infant if consumed by the mother for prolonged periods. Most briefly used opiate analogues appear to have little clinical effect. However, those opiate derivatives with excellent oral bioavailability and slow body clearance (e.g., methadone) or active metabolites with slow body clearance (e.g., meperidine) should be avoided during breastfeeding. The breastfeeding infants of mothers who receive these opiate analgesics may be more likely to manifest lethargy, poor feeding, and possibly apnea and cyanosis, underscoring the importance of administering other analogues as needed. It has been suggested that women receiving methadone maintenance doses take a daily dose after the last breast feeding in the evening because the methadone levels in breast milk peak about 4 hours after the administration of the drug orally. In choosing the best opioid for a breast-feeding mother, the physiochemical characteristics of the available narcotics should be taken into consideration. For instance, codeine is well absorbed and exhibits virtually no protein binding. Hydrocodone is also well absorbed, and the extent of protein binding is unknown. Alternatively, oxycodone is 60% to 85% absorbed and is 45% protein bound. Based on these properties, oxycodone appears to be the best choice for a nursing mother. Of note, maternal codeine use has been associated with the death of a breast-fed infant, although an increased rate of maternal metabolism of codeine to morphine likely played an important role in this scenario.[26]

NONTHERAPEUTIC AGENTS IN BREAST MILK

Caffeine

One hour after the ingestion of an average cup of coffee, a peak breast milk caffeine level of about 1.5 mg/mL is reached. Caffeine levels in breast milk are about half the corresponding maternal blood level. Although the daily amount of caffeine consumed by a nursing infant might be small, the long half-life of caffeine could cause symptoms such as wakefulness or jitteriness and might be considered in the evaluation of infants whose mothers consume large quantities of caffeine-containing products (e.g., cola, diet aids, coffee, and tea).

Ingredients of Cigarettes

The nicotine content of breast milk from women smoking one pack per day has been found to be about 100 to 500 parts per billion. No symptoms have been ascribed to this degree of contamination. Thiocyanate, which is elevated in the blood of smoking women, does not appear in elevated amounts in their breast milk.

Ethanol

Ethanol, a small molecule, is freely diffused into breast milk and achieves levels equivalent to those in blood. The metabolite acetaldehyde does not appear in breast milk. Excessive maternal ethanol intake may depress the nursing infant's central nervous system.

ENVIRONMENTAL POLLUTANTS IN BREAST MILK

See Chapter 12.

Lead

Lead has been found in both bovine and human milk as well as commercial infant formulas. The lead content of human milk has remained rather constant during the past four decades, in contrast to the levels of some other pollutants. One study found the lead level in human milk in the United States to be about 0.03 g/mL. There are no reports of signs and symptoms of lead toxicity from this source.

Mercury

Metallic or inorganic mercury poisoning in adults is usually associated with occupational exposure. There are no reports of metallic mercury poisoning from the consumption of breast milk. Organic mercury—more specifically, methyl mercury—has been used industrially in fungicides, pulp and paper factories, and chloralkali plants. In the late 1950s, Minamata Bay, Japan, was contaminated with industrial waste containing methyl mercury; the compound found its way into humans through contaminated fish. There was a high incidence of neurologic abnormalities in children born in this area, probably related to in utero exposure to the chemical rather than exposure during lactation. Methyl mercury was found in breast milk at a concentration of about 5% of that in blood; the half-life for the disappearance of mercury from breast milk was estimated to be about 70 days.

Several epidemics in Iraq in the past 15 years were traceable to the contamination of grains with methyl mercury fungicides. A number of nursing infants ingested enough methyl mercury in breast milk to achieve blood levels above the toxic limit.

Pesticides

Organic pesticides are concentrated in body fat. Breast milk production, with its export of large quantities of lipid, is an efficient way for a woman to rid her body of these poisons.[50] The nursing human infant thus becomes the highest animal in the "food chain." Dichlorodiphenyl trichloroethane (DDT) was first identified in breast milk in 1951, and the levels have been falling slowly since its use was restricted in North America in the early 1970s. Current levels of DDT in breast milk vary geographically and are related to the agricultural use of the compound. In Canada in 1979, the average level of DDT in breast milk was 44 ng/g. A 5-kg infant ingesting 1 kg of breast milk each day would thus take in about 0.009 mg/kg per day. The recommendation of the Food and Agriculture Organization and World Health Organization for the maximal allowable intake by an adult is about 0.005 mg/kg per day. Nevertheless, there are no known harmful effects to the infant from the ingestion of breast milk contaminated to this degree.

Many other pesticides have been found in breast milk, reflecting their commercial use in a particular region or country. For instance, concentrations of dieldrin, which was banned in the United States after 1974, are decreasing in breast milk.

Industrial Byproducts

The extremely toxic dioxin TCDD (2,3,7,8-tetrachlorodibenzo-p-dioxin) caused environmental contamination in Seveso, Italy in 1976. Chloracne developed in children who were directly exposed; further effects remain to be determined. This toxin has been found in breast milk.

There has been great public interest in the polychlorinated biphenyls (PCBs). This class of compound has had 50 years of industrial use, primarily in the manufacture of electric apparatuses (transformers, capacitors), although such use is declining. Because of the contamination of rivers and lakes by industrial effluents, PCBs have been widely distributed in freshwater fish and those animals that eat them. As with organic pesticides, PCBs remain in body fat stores and are excreted with the fat of breast milk. An epidemic of poisoning by PCBs (Yusho disease) occurred in 1968 in Japan when a commercial rice oil product was inadvertently contaminated with PCBs. The fetuses exposed in utero suffered growth restriction both antenatally and postnatally. Several infants whose only exposure was from breast milk had weakness and apathy. It is of great concern that the breast milk levels of PCBs in North America appear to be increasing. In Canada in 1979, the average PCB level in breast milk was 12 ng/g, whereas presently women who are exposed occupationally to PCBs or consume game fish from contaminated waters may have much higher levels in their breast milk.

The polybrominated biphenyls (PBBs) received attention as the result of an incident in Michigan in 1973 and 1974 in which several hundred pounds of PBBs, normally used as fire retardants in the plastics industry, accidentally contaminated cattle feed, resulting in the widespread intoxication of farm animals. PBBs have the usual propensity to lodge in fat tissue and persist in the body. To date, no ill effects have been noted in infants exposed to PBBs through their mothers' milk. In Michigan, the surveillance of PBB in breast milk has provided an accurate picture of the contamination of the general population. This method of epidemiologic analysis of fat-soluble poisons is highly recommended because the collection of milk samples is far easier than that of adipose tissue specimens. The levels of PBB in breast milk in the contaminated areas of Michigan averaged 0.07 parts per million.

Conclusions Concerning Breast Feeding and Maternal Drug Therapy

As with the fetus in utero, the nursing infant is exposed to nearly everything entering the body of its mother. The dangers, especially over the long term, are unclear. Environmental pollutants are almost impossible to avoid, and the elimination of nontherapeutic (recreational) compounds involves changing lifestyles. Drug administration is the easiest to control, but often a difficult choice must be made between maternal therapy and potential harm to the infant. The following simple guidelines should be observed.

1. Therapy should be with single agents if possible. In the case of long-term therapy, consideration should be given to monitoring the infant's activity and growth.
2. The physiochemical characteristics of multiple drugs within a given therapeutic class should be evaluated. Based on these properties, the drug least likely to pass into breast milk should be prescribed.
3. Attempt to minimize the dosage to the infant—avoid nursing at maternal peak plasma levels, and use the lowest effective dose.
4. Signs and symptoms in a nursing child should be correlated with maternal drug ingestion. In investigations, it is very useful to measure the levels of the drug and its metabolites in the infant's body fluids rather than at isolated times in maternal blood or breast milk.

PART 2

Infants of Substance-Abusing Mothers

Emmalee S. Bandstra and Veronica H. Accornero

CLINICIAN'S ROLE IN PERINATAL SUBSTANCE ABUSE

Numerous legal, illegal, and diverted prescription drugs have the potential for abuse by pregnant women with adverse effects on the developing fetus. Highlighted in this chapter are the current major drugs of abuse during pregnancy: alcohol, tobacco, marijuana, cocaine, amphetamines, and opioids. Regional differences in drug use patterns and preferences make it imperative for clinicians to work closely with other professionals in their communities and regions to develop a multilevel medical, legal, and psychosocial response. Screening by maternal self-report and toxicologic assays for substance abuse should be conducted when indicated, but with the intent to improve maternal-fetal care, not to impose punitive measures.

Ideally, women of childbearing age should be made aware that they and their sexual partners should curtail substance use before conception. Pregnant drug-using women should be counseled at the earliest opportunity to abstain completely from all injurious substances and to seek prenatal care. Referral to support groups and drug rehabilitation, as well as periodic random drug screens, should be incorporated into patient care plans as appropriate. Attention to adequate dietary intake and supplemental prenatal vitamins should be stressed and special emphasis should be placed on serology testing for syphilis and hepatitis B and C, and screening for human immunodeficiency virus (HIV) with pre- and post-test counseling. When clinically appropriate, complete blood count with differential; urine for urinalysis, culture, and sensitivity; Papanicolaou smear; gonorrhea and chlamydia tests; maternal blood pressure, electrocardiogram, and liver function tests; maternal serum α-fetoprotein screening; ultrasound screening for fetal anomalies and growth pattern; and chorionic villus sampling or amniocentesis with fetal karyotyping should be provided. Because catastrophic obstetric complications can accompany drug abuse, the pregnant substance-abusing mother should be specifically made aware of the signs of antepartum hemorrhage, premature rupture of membranes, premature labor onset, and meconium-stained amniotic fluid so that prompt diagnosis and treatment can ensue.

Identification of the substance-abusing mother is the first step in breaking the unrelenting cycle of reproductive morbidity or mortality that often accompanies drug abuse. A woman entrenched in the substance-abusing lifestyle may not seek prenatal care, even when it is available, because of guilt or fear of legal reprisals, such as incarceration and child welfare proceedings. If she is not engaged during prenatal care, the substance-abusing mother's hospitalization at delivery may afford the only window of opportunity to evaluate her health and psychosocial status and the medical and developmental status of her infant for appropriate multidisciplinary referrals. Obstetricians can be instrumental in providing postpartum counseling for prevention of future drug-exposed pregnancies, sexually transmitted diseases, and HIV infection.

Current limitations of maternal self-report, selective screening criteria, and available toxicology assays preclude clinical identification of all affected infants. Physicians should become well informed about patterns of substance abuse in their community. By incorporating skillful interviewing techniques and appropriate toxicologic screening to identify perinatal substance abuse, knowing the statutory obligation to report drug-exposed infants to child protection authorities, and developing specific medical intervention strategies and viable referral patterns for substance-abusing women and their offspring, physicians treating mothers and their babies can work collaboratively to provide the impetus for change in addressing this crucial perinatal issue.

Clinicians should consider the inherent limitations of both animal and human literature in providing definitive answers on the effects of individual drugs and drug interactions. Preclinical basic science studies using animal models can test the teratogenicity of a drug under controlled laboratory settings, but interspecies variations constrain application to humans. Clinical investigations provide naturalistic environments for studying the effects of drugs of abuse, but despite concerted efforts to design and implement well-controlled studies with adequate control groups, numerous confounding factors affect interpretation of results, even with careful study designs and statistical controls. Clinical guidelines for obstetric and neonatal screening are generally based on conditions often associated with perinatal substance abuse, such as self-admitted alcohol or drug abuse, inadequate or no prenatal care, sexually transmitted diseases, premature onset of labor, abruptio placentae, intrauterine growth restriction, congenital malformations, and overt signs of withdrawal. However, these criteria fail to detect a large number of affected pregnancies. Self-reporting of substance abuse may be unreliable because of poor maternal recall and fear of reprisals from the legal, medical, and social welfare systems. However, the value of conducting a nonjudgmental and culturally sensitive interview with the mother to elicit a history of substance abuse and associated comorbidities should not be underestimated. In some cases, maternal self-report may be the only available means of identification of a mother and fetus at risk. Reliance on the physical examination or the clinical condition of the infant to indicate when toxicology screening should be performed is also inadequate. Intrauterine growth restriction, microcephaly, prematurity, and congenital malformations may be associated with prenatal substance exposure, but not all affected infants present with such obvious medical complications. Abnormal neurobehavioral signs and overt withdrawal are not uniformly present even in narcotic-exposed infants.

Although urine toxicology screening is useful for clinical and research purposes, urinary excretion of metabolites may be detectable only for several days (e.g., benzoylecgonine) or even weeks (e.g., cannabinoids). One cannot expect to ascertain early pregnancy use or even relatively recent use if the metabolite concentration does not reach the detection threshold. Infant meconium provides a wider window of detection of gestational exposure, presumably as remote as the second trimester. Maternal and infant hair samples may provide an even wider window and some insight into time course and perhaps quantification of in utero drug exposure. However, hair assays are generally reserved for research settings and have numerous technical and interpretive limitations.

The most significant problem in interpreting clinical studies of in utero substance exposure is the handling of confounding variables, such as maternal polydrug use, sexually transmitted diseases, chronic malnutrition, and cocaine binges with episodic starvation. Polydrug exposure is common among pregnant substance abusers, and combinations of two or more agents may be more ominous than single-agent exposure (e.g., concurrent cocaine and alcohol use). Cocaethylene, a pharmacologically active metabolite of cocaine produced in the presence of ethyl alcohol, produces enhanced euphoria and appears to result in a high prevalence of cocaine-related emergencies or death in adults. This compound has been detected in neonatal meconium and hair and may correlate with higher risk to the developing infant and child.

Similarly, it is difficult to disentangle the many social and environmental factors that accompany perinatal substance abuse. Although abuse of alcohol, tobacco, and illicit drugs occurs in all races, ethnicities, and socioeconomic strata, substance-abusing mothers at greatest risk are those who are mired in poverty and its associated conditions, such as lack of food, shelter, and clothing; increased stress; poor self-esteem and poor coping skills; depression and other comorbid psychiatric disorders, exposure to physical, sexual, and domestic violence; increased risk for contracting HIV, acquired immunodeficiency syndrome (AIDS), and sexually transmitted diseases; poor education, illiteracy, and joblessness; and inadequate access to culturally and linguistically appropriate health, social, legal, and addiction-treatment services.

This chapter seeks to provide an overview of the drugs of interest and to emphasize specific diagnostic criteria and interventions as appropriate (e.g., the recognition of fetal alcohol syndrome [FAS] or the treatment for neonatal abstinence syndrome). Recommendations regarding prevention and intervention, including multidisciplinary services that should be provided for the mother and her substance-exposed infant, are also provided. Over the past few decades, research and service demonstration programs and community-based initiatives throughout the nation have sought to improve delivery through enhancing prevention and intervention networks to address the compelling issues unique to perinatal substance abuse, but challenges remain, especially in economically depressed areas. The most successful programs are multidisciplinary and provide a comprehensive range of barrier-free medical, social, psychological, chemical dependency treatment, and vocational and educational services to the pregnant and postpartum mother, her infant, and her family for an extended period. In 1990, Finnegan and colleagues described their schema for the multidisciplinary treatment of opioid dependence in the perinatal period.[65] Similar programs have been implemented in other populations of substance-abusing mothers. Figure 38-10 depicts the prevention and intervention model of direct, referral, and wrap-around community-based services provided by the University of Miami Perinatal Chemical Addiction Research and Educational Program serving pregnant and postpartum women with substance abuse disorders and mental health problems, their infants, and their families.

ALCOHOL

Prevalence of Fetal Alcohol Syndrome

FAS is the leading identifiable nonhereditary cause of mental retardation and neurologic deficit in the Western world. Initially described more than three decades ago by separate investigative teams in France and the United States, FAS has the following hallmarks: (1) growth restriction, (2) specific midfacial features (short palpebral fissures, smooth indistinct philtrum, thin upper lip vermilion border), and (3) adverse brain effects resulting in mental retardation. Although not specifically mentioned in the FAS triad, congenital defects of other major organs have also been noted. Features consistent with FAS in humans have been reproduced in animal models of gestational ethanol exposure (Fig. 38-11).[153] Studies in mice and chicks have shown that alcohol exposure at specific stages of early embryonic development leads to apoptosis of cranial nerve crest cells destined to give rise to facial structures, perhaps because of localized retinoic acid deficiency, free radical damage, or interference with intracellular communication.[146]

According to the 2007 National Survey on Drug Use and Health, pregnant women aged 15 to 44 reported alcohol use at a rate of 11.6%, with 3.7% reporting binge drinking and 0.7% reporting heavy drinking in the month before the survey.[152] In comparison, rates were considerably higher for similarly aged nonpregnant women (53%, 24.1%, and 5.5%, respectively), but alcohol use during pregnancy is a significant clinical concern. Binge drinking is defined as drinking five or more drinks on the same occasion (i.e., at the same time or within a couple of hours) on at least 1 day in the past 30 days. Heavy drinking is defined as the equivalent of binge drinking on each of 5 or more days in the past 30 days.[152] Although the current recommendation for a healthy lifestyle for men is the ingestion of no more than two drinks per day, for nonpregnant women, it is no more than one drink per day. However, there is no safe limit established for women who are pregnant or who are likely to become pregnant, and such women are well advised to abstain from alcohol and other potentially deleterious substances entirely. Although definitions vary, for most clinical

studies of prenatal alcohol exposure, more than two drinks per day exceeds what is considered moderate alcohol consumption during pregnancy, and binge drinking is considered a significant separate risk factor.

Estimated from 29 prospective studies, the worldwide incidence of FAS is 0.97 cases per 1000 live births in the general obstetric population and 4.3% among heavy drinkers.[1] In the United States, the general incidence of FAS is reported to be more than 20-fold higher than in other countries (1.95 per 1000 versus 0.08 per 1000). Furthermore, low socioeconomic status (SES) is a significant risk factor. In the United States, the reported incidence of FAS among low SES groups, represented predominantly by African Americans and Native Americans, is more than 10 times higher than that of middle and upper SES, predominantly white, populations (2.29 versus 0.26 per 1000). Conditions associated with low SES (such as poor general health, increased stress, and nutritional deficiencies), a more severe pattern of alcohol ingestion, and concomitant smoking and other drug use are hypothesized to exacerbate the teratogenicity of heavy alcohol intake through mechanisms linked to hypoxia and free radical generation, leading to cell damage within the fetus. Although the risk for FAS may be relatively low even among heavy drinkers, once a woman has had one infant with FAS, her risk for having a subsequent infant with FAS may be as high as 60% to 70% if she continues to drink. Studies have shown a higher rate of

offspring with FAS in women older than 30 years, perhaps because of altered physiology or increased maternal morbidity associated with lengthy drinking histories. Obstetric consequences of heavy drinking include life-threatening increased risk for spontaneous abortions, abruptio placentae, and alcohol-related birth defects. In about 30% to 40% of infants of heavy drinkers, the cognitive and neurobehavioral deficits are milder and may occur with or without classic facial features. The original term for this less severe expression was *fetal alcohol effects* (FAE). These observations have prompted speculation regarding genetic and individual susceptibility differences in the expression of effects of alcohol in the mother and fetus, such as maternal age, diet, serious medical conditions, other toxic exposures, and environmental factors, especially those associated with low SES.

Fetal Alcohol Spectrum Disorders

Fetal alcohol spectrum disorders (FASD) is an umbrella term for the range of physical, mental, behavioral, and learning deficits that can occur in an individual whose mother drank alcohol during pregnancy, but FASD is not intended as a clinical diagnosis. In 1996, the Institute of Medicine published specific diagnostic criteria for FAS, partial FAS, alcohol-related birth defects (ARBD), and alcohol-related neurodevelopmental disorder (ARND) as detailed in Figure 38-12.[2,40]

Despite widespread awareness of FAS, clinicians frequently fail to recognize the syndrome and its partial manifestations in the newborn period. The stigmata are more easily diagnosed in the early- to mid-childhood years, but the distinctive dysmorphic signs become less pronounced as the child continues to mature. Diagnosing FAS for the first time in late adolescence and adulthood is often difficult without the availability of earlier photographs and medical and developmental assessments. Various techniques have been used to document facial dysmorphology for clinical and research purposes, including conventionally performed measurements with a hand-held ruler by a highly trained dysmorphologist and newer, reportedly more consistent, stereophotogrammetric methods.

Central Nervous System Effects

Investigations using animal models of fetal alcohol exposure have shown significant abnormalities of midline brain development. Neuropathologic studies in humans with FAS have also demonstrated significant brain anomalies, such as micrencephaly, anencephaly, agenesis of the corpus callosum, holoprosencephaly-arhinencephaly, cerebellar dysgenesis, and leptomeningeal glioneuronal heterotopias. Magnetic resonance imaging (MRI) of patients with FAS has shown midline anomalies of the corpus callosum, cavum septi pellucidi, and cavum vergae, as well as micrencephaly, ventriculomegaly, and hypoplasia of the inferior olivary eminences.[154] Morphometric variations in the corpus callosum on MRI scans have been correlated with specific neuropsychological deficits in patients with FAS.[26] In a study of 19 nonretarded individuals with prenatal alcohol exposure, positron emission tomography scanning showed group decreases in relative regional cerebral metabolic rates in the thalamus and basal ganglia compared with controls, even though only one of the alcohol-exposed cases had MRI evidence of a structural abnormality (thinned corpus callosum).[36]

Infants born to mothers who chronically ingested alcohol throughout pregnancy up until delivery may also show signs consistent with intoxication and postnatal withdrawal, such as restlessness, excessive mouthing, inconsolable crying, tremors, abnormal reflexes, and hypertonia. The treatment of neonates with acute alcohol withdrawal includes the same monitoring and recommendations described in neonatal abstinence syndrome (see “Opioids,” later), except that sedation rather than opioid substitution is the preferred pharmacotherapy, if needed.

Prenatal and Postnatal Growth Effects

Most studies confirm that gestational alcohol exposure is associated with deficits in infant weight, length, and head circumference at birth and during early infancy, even with control for other drugs of abuse. The Pittsburgh Maternal Health Practices and Child Development Study showed an apparent linear association between prenatal alcohol exposure and growth, with effects measured at exposure levels of less than one drink per day, thus reinforcing the potential teratogenicity of alcohol even at low levels. Furthermore, prenatal alcohol exposure continued to be a significant predictor of decreased growth at age 14 years in this predominantly low-income cohort.[48] In contrast, prenatal alcohol-related deficits in birthweight, length, and head circumference did not persist beyond infancy in the large, middle-class cohort of the Seattle Longitudinal Study on Alcohol and Pregnancy,[131] suggesting that SES may play a significant role in ameliorating in utero alcohol exposure’s impact on long-term growth deficits in more advantaged populations.

Neurobehavioral and Developmental Effects in Infancy

Amount, timing, and pattern of gestational alcohol exposure appear to be relevant in determining the effects on the infant. Electroencephalographic studies in preterm and term infants exposed in utero to varying quantities of alcohol have suggested that the intermittent ingestion of large quantities of alcohol might be more detrimental to fetal brain development than more continuous ingestion of smaller quantities.[82] Prenatal alcohol exposure during the first trimester has been associated with increased arousal and indeterminant sleep with decreased quiet and active sleep periods.[133] Although light to moderate gestational alcohol exposure has generally shown no or few convincing effects on infant neurobehavior assessed by the Brazelton Newborn Behavioral Assessment Scale (BNBAS), a study of infants born to heavier drinkers demonstrated difficulties with habituation and arousal.[150] Another series of studies on infants exposed to alcohol throughout pregnancy, compared with controls whose mothers stopped drinking by the second trimester, showed worse BNBAS scores on state control, need for stimulation, motor tone, tremulousness, and asymmetric reflexes that persisted over the first month.[39] A meta-analysis of the effects of varying exposure levels (less than 1 drink per day, 1 to 1.99 drinks per day, and 2 drinks or more per day) on the

* Adapted from *Fetal Alcohol Syndrome: Diagnosis, Epidemiology, Prevention, and Treatment.* 1996;4–5. Letter designations in the figure indicate the following:

A. Confirmed maternal alcohol exposure indicates a pattern of excessive intake characterized by substantial, regular intake or heavy episodic drinking. Evidence of this pattern may include frequent episodes of intoxication, development of tolerance or withdrawal, social problems related to drinking, legal problems related to drinking, engaging in physically hazardous behavior while drinking, or alcohol-related medical problems such as hepatic disease.

B. Evidence of a characteristic pattern of facial anomalies that includes features such as short palpebral fissures and abnormalites in the premaxillary zone (e.g., flat uppper lip, flattened philtrum, and flat midface).

C. Evidence of growth restriction, including at least one of the following:
- low birthweight for gestational age
- decelerating weight over time not caused by nutrition
- disproportional low weight to height

D. Evidence of CNS neurodevelopmental abnormalities, including at least one of the following:
- decreased cranial size at birth
- structural brain abnormalities (e.g., microcephaly, partial or complete agenesis of the corpus callosum, cerebellar hypoplasia)
- neurologic hard or soft signs (as age appropriate), such as impaired fine motor skills, neurosensory hearing loss, poor tandem gait, poor eye-hand coordination

E. Evidence of a complex pattern of behavior or cognitive abnormalities that are inconsistent with developmental level and cannot be explained by familial background or environment alone, such as learning difficulites; deficits in school performance; poor impulse control; problems in social perception; deficits in higher level receptive and expressive language; poor capacity for abstraction or metacognition; specific deficits in mathematical skills; or problems in memory, attention, or judgment.

F. Birth defects associated with alcohol exposure include:

Cardiac	Atrial septal defect Ventricular septal defect	Aberrant great vessels Tetralogy of Fallot
Skeletal	Hypoplastic nails Shortened fifth digit Radioulnar synostosis Flexion contractures Camptodactyly	Clinodactyly Pectus excavatum and carinatum Klippel-Feil syndrome Hemivertebrae Scoliosis
Renal	Aplastic, dysplastic, hypoplastic kidneys Horseshoe kidneys	Ureteral duplications Hydronephrosis
Ocular	Strabismus Retinal vascular anomalies	Refractive problems secondary to small globe
Auditory	Conductive hearing loss	Neurosensory hearing loss
Other	Virtually every malformation has been described in some patient with FAS. The etiologic specificity of most of these anomalies to alcohol teratogenesis remains uncertain.	

†Alcohol-related effects indicate clinical conditions in which there is a history of maternal alcohol exposure, and where clinical or animal research has linked maternal alcohol ingestion to an observed outcome. There are two categories, alcohol-related neurodevelopmental disorder and alcohol-related birth defects, which may co-occur. If both diagnoses are present, then both diagnoses should be rendered.

Figure 38–12. Diagnostic classification of fetal alcohol syndrome (FAS) and alcohol-related effects. CNS, central nervous system.

Mental Development Index (MDI) of the Bayley Scales of Infant Development showed that fetal alcohol exposure was associated with a significantly lower MDI among 12- to 13-month-olds at all three exposure levels.[156]

Neuropsychological and Behavioral Effects in Childhood and Adolescence

Streissguth and associates first traced the natural history of FAS and FAE into adolescence and early adulthood.[149] In an initial, small series of 61 patients, the characteristic facial features of FAS became less distinct with maturation, and the weight approached normal, but head growth and height still lagged in many of the patients. Mean IQ was 68, with a range of 20 to 105—the more severely affected being the individuals with full-blown FAS. The adolescents and adults with FAS/FAE also demonstrated elementary school level reading, spelling, and arithmetic skills and maladaptive behavior.[149] In the larger Seattle Longitudinal Study, the offspring of mothers who had an average daily ingestion of two or more drinks (1 ounce or more of absolute alcohol) demonstrated a seven-point covariate adjusted decrement (nearly half a standard deviation) in IQ by age 7½ years. Furthermore, learning problems occurred more often among the young school-aged children whose mothers reported binge drinking during pregnancy.[151]

In a review of neuropsychological findings associated with FAS/ARND, Jacobson and Jacobson highlighted specific deficits in sustained attention (especially on tasks requiring active recall of information or response inhibition), focused attention, cognitive flexibility, planning, learning and memory, and socioemotional function.[83] Individuals exposed prenatally to alcohol also show impairments in performing relatively complex and novel tasks that tap executive functioning, defined as the ability to plan and guide behavior to achieve a goal in an efficient manner.[92] In a clinically referred population of adolescents and young adults with FAS/ARND, comorbid attention deficit/hyperactivity disorder was found in nearly three-fourths of the cases, in contrast to only 36% of referrals without FAS/ARND.[31]

Animal models of prenatal alcohol exposure have demonstrated numerous sociobehavioral deficits, including sexually dimorphic changes in play, delays in induction of maternal behavior, and increased aggression in males.[91] A study showed increased aggressive and externalizing behavior in 6-year-old children exposed prenatally to as little as one alcoholic beverage per week compared with an unexposed control group.[147] As individuals with prenatal alcohol exposure, especially those with FAS, progress into later adolescence and adulthood, deficits in "real life" socioemotional functioning emerge.[91] In prenatally alcohol-exposed adolescents and young adults, impulsivity and irritable temperament, inappropriate sexual behavior, criminal activities, depression, suicidal tendencies, and difficulties in caring for children have been observed to be more frequent than in unexposed individuals. Furthermore, prenatal alcohol exposure appears to be a risk factor for developing drinking problems in young adulthood, even after controlling for other relevant covariates.[11]

Thus, numerous deficits in neuropsychological function have been observed in follow-up studies of children, adolescents, and adults exposed in utero to alcohol. The effects represent a spectrum of teratologic impact, and the outcomes appear to be a function of the amount, timing, and pattern of toxic exposure and the environment as well as genetic factors. Considerable investigative work is still needed to establish the continuum of adverse effects of fetal alcohol exposure, at varying exposure levels and developmental stages of the organism, and to elucidate the underlying mechanisms of observed deficits in structure, function, or altered developmental trajectory of affected offspring.

Recommendations for Prevention and Intervention

The AAP recommends abstinence from alcohol preconceptionally and during pregnancy, screening of all pregnant women for alcohol use, and referral of pregnant alcohol abusers for assessment and treatment.[2] This recommendation is defensible because well-designed clinical studies have described fetal growth disturbances and ARND, even at relatively low levels of alcohol exposure during pregnancy. Furthermore, it is clear that FAS and its partial manifestations are irreversible lifelong conditions that are entirely preventable if a woman does not drink alcohol while she is pregnant. Guidelines for screening and management of FAS include universal screening of pregnant women for alcohol use so that appropriate management can be provided.[2] A brief, easily administered, standardized questionnaire such as the TWEAK (Box 38-3) is applicable to nearly all obstetric settings for the identification of pregnant women at risk so that referrals can be made for further drug abuse and psychosocial assessment and treatment.[27] Because self-report may not identify all at-risk cases, further research is needed on biomarkers for detecting fetal alcohol exposure. A novel test

BOX 38–3 **TWEAK Problem Drinking Questionnaire***

T (Tolerance)	How many drinks does it take before you begin to feel the first effects of alcohol?	≥3 drinks = 2 points
W (Worried)	Have close friends or relatives worried or complained about your drinking in the past year?	Yes = 2 points
E (Eye-opener)	Do you sometimes take a drink in the morning when you first get up?	Yes = 1 point
A (Amnesia)	Has a friend or family member ever told you about things you said or did while you were drinking that you could not remember?	Yes = 1 point
K ("Kut" down)	Do you sometimes feel the need to cut down on your drinking?	Yes = 1 point

---

*(From Bradley KA, et al: Alcohol screening questionnaires in women: a critical review, *JAMA* 280:166, 1998). Score of ≥2 indicates problem drinking in women: A standard drink is defined as 12 ounces of beer, 5 ounces of wine, or 1.5 ounces of spirit.

capable of detecting fetal fatty acid ethyl esters in the meconium of newborns of heavy alcohol users may be useful for identification of infants in need of early health, developmental, and psychosocial intervention and may enhance clinical research involving prenatal drug and alcohol exposure.[17]

An American College of Obstetricians and Gynecologists committee opinion states that there is an ethical obligation to provide services to women with at-risk alcohol use and recommends incorporation of a universal screening and the BNI-ART Institute Intervention (Brief Negotiated Interview and Active Referral to Treatment) algorithm into clinical practice.[157] Additional guidelines focus on prevention of alcohol abuse by adolescents and women of childbearing age, including education at all levels regarding the deleterious effects of alcohol on the developing fetus; provision of appropriate multidisciplinary health, neurodevelopmental, and social services to affected children and their families; fostering of federal and state legislation aimed at providing warnings and information about FAS in public places and in alcohol advertisements; and training of physicians and health professionals in FAS screening and diagnosis in affected infants and their siblings.

TOBACCO

Prevalence and Pharmacology

Despite a large public health antismoking campaign, tobacco remains the most widely used addictive substance. According to the 2007 National Survey on Drug Use and Health (NSDUH), an estimated 70.9 million Americans, 28.6% of the population, reported past-month tobacco use. Of the thousands of chemical constituents in tobacco, nicotine is the primary psychoactive chemical responsible for its addictive properties. Nicotine is rapidly absorbed through the lungs, permeating the brain within seconds of inhalation; it is absorbed more slowly through oral mucosa and skin. Nicotine binds to nicotinic acetylcholine receptors in the brain, stimulating the release of multiple neurotransmitters including acetylcholine, norepinephrine, γ-aminobutyric acid (GABA), and glutamate. As with other drugs of abuse, nicotine directly stimulates dopamine release in the mesolimbic dopaminergic pathway, or the reward center, and may indirectly sustain dopamine levels in this region through actions on GABA and glutamate-containing cells.[107] Nicotine also acts in the periphery, stimulating release of epinephrine from the adrenal cortex, which initiates a physiologic response consistent with the flight-or-fight reaction, including increased heart rate, blood pressure, and respiration. It also suppresses insulin release, which may produce hyperglycemia and affect appetite.

Tobacco is highly addictive. Regular tobacco use produces tolerance as well as withdrawal symptoms, including irritability, headache, nausea, and craving. Tobacco remains the leading cause of preventable premature death in adults, due to cancer, chronic respiratory diseases, and cardiovascular disease, including stroke, heart attack, and certain aneurysms. Passive exposure to tobacco smoke has also proved to be a health hazard in infants, children, and adults. According to the 2004 Surgeon General's report, tobacco smoking is the cause of 440,000 deaths annually, with health care costs reaching $75 billion.

In 1992, the National Pregnancy and Health Survey performed by the National Institute on Drug Abuse (NIDA) estimated the prevalence of prenatal tobacco use to be 20.4%. In the 2007 NSDUH, 16.4% of women reported using tobacco during pregnancy. It has been well established, however, that self-report data underestimate the prevalence of prenatal tobacco exposure, as evidenced by high deception rates when biomarkers are used. Prenatal tobacco use is more prevalent in younger women and in white women compared with those of African-American or Hispanic heritage. Smoking during pregnancy is also strongly associated with lower educational attainment and income. Although pregnancy provides a powerful motivator for some women to quit smoking, data suggest that many continue throughout pregnancy, attesting to tobacco's highly addictive properties. Of smokers who abstain during pregnancy, a large number resume smoking in the months after delivery.

Fetal Effects

Prenatal tobacco use has numerous deleterious effects on the fetus. Maternal appetite suppression and poor overall nutritional status negatively affect fetal growth and development. A powerful vasoconstrictor, nicotine reduces blood flow through uterine and umbilical arteries, diminishing oxygen supply to the fetus and resulting in hypoxic and ischemic events. Nicotine-associated placental structural and functional abnormalities further restrict blood supply and decrease transplacental amino acid transfer. Increased carbon monoxide levels hinder delivery of oxygen to fetal tissue by binding with hemoglobin to form carboxyhemoglobin. Moreover, prenatal tobacco smoking is often associated with additional risk factors, including limited prenatal care, lower income status, and use of other substances of abuse.

In addition to affecting the maternal-fetal system, nicotine affects the fetus directly. Nicotine crosses the placental barrier without difficulty and is found at significantly elevated levels in amniotic fluid and fetal blood compared with maternal plasma levels. Additionally, nicotinic acetylcholine receptors are present very early in gestation and are thought to be important in normal brain development. Stimulation of these receptors during gestation may produce alteration in neuronal ontogenesis, cell differentiation and migration, and modified synaptic functioning. Slotkin reviewed evidence from animal models supporting the direct neurotoxin effect of nicotine on fetal development, independent of its hypoxic and ischemic effects.[142] In these models, prenatal nicotine exposure, even at levels that did not produce fetal growth restriction, resulted in cell damage as well as loss, presumably owing to a premature signaling of the switch from cell proliferation to cell differentiation and induced apoptosis. Prenatal nicotine exposure has also been linked to upregulation of cholinergic receptors and lasting hypoactivity in cholinergic functioning. Because of the cholinergic interface with multiple neurotransmitter systems, diminished dopamine and norepinephrine functioning has also been observed. Additionally, in the periphery, gestational exposure to nicotine may alter the responsivity of the adrenal gland to episodes of hypoxia.

Pregnancy and Delivery Complications

Numerous pregnancy and delivery complications have been associated with maternal smoking, including perinatal death, spontaneous abortion, stillbirth, abruptio placentae, placenta previa, premature delivery, and fetal growth restriction. Interestingly, smoking appears to offer some protection against preeclampsia.[55] The relationship between maternal smoking and decreased fetal growth is well established. Women who smoke during pregnancy have a significantly higher risk for delivering an infant who is small for gestational age than nonsmokers, and infants born to smokers are significantly lighter than those of nonsmokers. The effect of maternal smoking on fetal growth appears to be dose dependent and separate from the impact on gestational age. Infant length and head circumference are also negatively affected by prenatal tobacco exposure,[72] although some studies suggest that in utero tobacco exposure affects weight to a greater degree. Tobacco-related decrements in fetal growth generally do not persist beyond the first few years of life.[72] In fact, there is evidence that prenatal tobacco exposure is related to obesity in childhood, a relationship that remains even after adjustment for factors such as birthweight, breastfeeding, diet, and parental size.[119]

Neonatal and Infant Complications

Prenatal tobacco exposure results in considerable infant morbidity and mortality, with increased risk for admission to a neonatal intensive care unit (NICU) because of higher rates of prematurity and intrauterine growth restriction and, once admitted, a longer stay, resulting in substantially higher neonatal costs. Additionally, the risk for neonatal death is higher in infants born to smokers than to nonsmokers.[37] Congenital malformations have not been consistently reported in tobacco-exposed infants, although an increased risk for oral clefts has been noted. Animal and human studies suggest that in utero tobacco exposure alters lung development and impairs lung function independent of postnatal tobacco exposure.[74,136] As summarized by Stocks and Dezateux,[148] structural and functional changes are likely to be responsible in part for the greater incidence of respiratory difficulties (such as wheezing, respiratory infection, and poor asthma control) observed in infants and children of mothers who smoke. Anderson and Cook[5] reviewed extensive evidence from several prospective and large case-control studies supporting a dose-dependent relationship between both prenatal and postnatal tobacco smoking and sudden infant death syndrome (SIDS). Although it is difficult to isolate the effects of prenatal and postnatal exposures, it is likely that prenatal nicotine exposure contributes uniquely to the risk for SIDS. Exposure to nicotine has been shown to modify cardiorespiratory control and diminish response to hypoxic events, which may result in greater susceptibility to SIDS.[142]

Neurobehavioral and Developmental Effects in Infancy

Maternal smoking during pregnancy negatively affects cognitive and behavioral development, beginning in infancy (see review by Olds[120]). Prenatal tobacco exposure has been related to neurobehavioral abnormalities in the neonatal period, including increased tremulousness, altered autonomic regulation, diminished auditory responsiveness, and decreased auditory habituation. Greater negative affect has also been noted in tobacco-exposed newborns.[135] Law and coworkers[94] found greater autonomic excitability, hypertonicity, and stress/abstinence symptoms, as measured by the NICU Network Neurobehavioral Scale, in a group of 1- to 2-day-old infants exposed primarily to tobacco. This study also documented a dose-response relationship between maternal salivary cotinine levels and stress/abstinence scores. The existence of a neonatal nicotine withdrawal syndrome has been suggested, particularly in the case of heavy tobacco exposure.

Delays in early infant development have also been reported in relationship to prenatal tobacco exposure. Prenatal tobacco exposure was found to be associated with lower verbal comprehension on the Bayley Scales of Infant Development at age 13 months after covariate adjustment. In another report, tobacco-exposed infants displayed poorer verbal comprehension and auditory response on the Bayley Scales at 12 months of age. Although the prenatal tobacco effect on auditory responding remained at 24 months, prenatal tobacco-related deficits in verbal development were no longer evident once postnatal influences were considered.[71] In one study with implications for future speech development, 8-month-old infants with moderate to heavy prenatal tobacco exposure (i.e., more than 10 cigarettes per day) were found to have double the risk for being a nonbabbler as unexposed infants.[118] Several other studies, however, have not shown prenatal tobacco-related deficits in early development.

Neuropsychological and Behavioral Effects in Childhood and Adolescence

The long-term cognitive outcomes of children exposed prenatally to tobacco remain somewhat equivocal because of variations in study designs, outcome measures, and control of potential confounding influences. Nevertheless, certain patterns in functioning have emerged among exposed children. Findings from the prospective, longitudinal Ottawa Prenatal Prospective Study (OPPS) suggest persistent tobacco-related deficits in general cognitive functioning, with specific effects on verbal abilities and auditory functioning, measured from early childhood through early to mid adolescence.[73] Altered auditory responding was observed in infancy in this cohort and continued into childhood, with the tobacco-exposed children showing poorer central auditory processing at 6 to 11 years of age and lower scores in reading, particularly involving tasks with auditory components. These findings were largely dose-related and evident even after control for potential confounding influences. In another cohort, prenatal tobacco was related to poorer verbal learning, design memory, problem solving, and eye-hand coordination at age 10 years.[41] Although some studies have reported a relationship between prenatal tobacco exposure and lower intellectual functioning, others indicate no effect, particularly after adjustment for factors such as maternal education and IQ.[28]

The association between maternal smoking during pregnancy and poor behavioral and psychological outcomes in children is well documented (see review by Button and colleagues[32]). Although greater internalizing symptoms have been noted, more consistent is the report of increased externalizing problems, such as aggression, hyperactivity, impulsivity, and inattention in prenatally tobacco-exposed children. In utero tobacco exposure has been linked to attention-deficit/hyperactivity disorder and disruptive behavior disorders (oppositional defiant disorder and conduct disorder) during childhood and adolescence and, to a lesser extent, antisocial behavior in adulthood. Accumulating evidence also suggests that in utero nicotine exposure increases risk for smoking among offspring. Although a direct biologic effect is plausible, the true etiologic role of prenatal tobacco exposure in these associations is unclear because of shared genetic risk and other possible confounding biologic and environmental influences.

Environmental Tobacco Smoke

A significant challenge in interpreting data on the effects of prenatal tobacco exposure, particularly the long-term effects, is the issue of environmental tobacco smoke. Although it is well known that most women who smoke during pregnancy continue smoking after delivery, many prenatal studies have failed to adequately consider the potential effect of postnatal environmental tobacco smoke exposure on infant and child outcomes. In studies that have addressed postnatal tobacco exposure, interpretation of findings is often limited because of difficulties in measuring environmental exposure (e.g., accurately determining the hours of exposure in and out of the home; size and ventilation of living space; limits of biologic markers in terms of exposure time), accounting for additional confounding influences, and statistically separating the effects of prenatal and postnatal exposures. It is, therefore, unclear in many studies whether the associated effects are attributable to maternal smoking during pregnancy, passive tobacco exposure postnatally, or an additive effect. Overall, postnatal environmental tobacco smoke exposure is quite common in early childhood. According to a recent report by the Surgeon General, roughly 60% of children aged 3 to 11 years are exposed to environmental tobacco smoke, and 25% live with at least one smoker. This report also summarizes evidence that suggests that childhood exposure to environmental tobacco smoke is strongly associated with respiratory difficulties, such as wheezing, infections, and asthma complications, as well as an increased risk for SIDS.[159] Because brain development continues throughout childhood and adolescence, it is plausible that postnatal environmental tobacco exposure may also result in lasting neurodevelopmental complications. Although few studies have adequately separated the effects of postnatal environmental exposure from those of prenatal active and passive tobacco smoking, there are data to suggest that postnatal environmental tobacco exposure is associated with poorer cognitive functioning in childhood and adolescence, independent of any prenatal effect.[162]

Prenatal environmental tobacco smoke exposure is also of concern but has been largely neglected in the literature. Prevalence data suggest that a large number of nonsmoking pregnant women may be exposed to environmental tobacco smoke.[159] Importantly, passive exposure to tobacco smoke during pregnancy can produce fetal nicotine concentrations comparable to those achieved with light active smoking by the mother.[122] Clinical studies show the impact of prenatal environmental tobacco exposure to be similar to that of active maternal smoking but to a lesser degree. A meta-analysis by Leonardi-Bee and colleagues[95] indicated a 22% increase in risk for low birthweight and a 33-g decrement in mean birthweight in relation to passive tobacco exposure during pregnancy (compared with a 200-g difference frequently observed in infants of active smokers).

Recommendations for Prevention and Intervention

Animal and human research studies indicate that maternal smoking during pregnancy alters fetal development and results in a number of perinatal complications with potential negative cognitive, behavioral, and physical health consequences that may persist into adulthood. Women should be counseled about the harmful effects of smoking during pregnancy and provided appropriate support for stopping as early in pregnancy as possible. Cessation of smoking early in pregnancy may diminish the impact of tobacco on fetal growth occurring mainly in the third trimester and on the structure and function of emerging nicotinic cholinergic receptors important in brain development. Studies have shown that smoking cessation during pregnancy reduces low birthweight and the risk for premature delivery.[105] One study documented the long-term benefits of smoking cessation, reporting higher scores on tests of cognitive abilities for 3-year-olds whose mothers stopped smoking during pregnancy compared with those whose mothers persisted.[137] Reduction in the number of cigarettes smoked without cessation does not appear to offer major benefits with regard to birth growth parameters unless very low levels of exposure are achieved.[56] Fortunately, effective smoking cessation interventions are available for pregnant women.[105] Relatively brief, psychosocial approaches adapted for use with pregnant women have yielded moderate success, particularly with light to moderate smokers.[66,112] Best practices for intervening with pregnant smokers include augmented counseling conducted within the “five As” framework (i.e., a five-step counseling approach—ask, advise, assess, assist, and arrange).[4,66,112] Innovative and more intensive behavioral interventions may be needed to achieve higher success rates in some women. Voucher-based incentives have been shown to increase abstinence rates in a low-income pregnant population.[52] In a systematic review of the literature, Lumley and associates[105] found that one intervention strategy that combined rewards with social support achieved higher quit rates than other approaches. Currently, there is insufficient evidence regarding the safety and efficacy of tobacco dependence medications in pregnant women to recommend routine use. Given the high rate of relapse postpartum and the detrimental effects of environmental tobacco smoke, it is important to continue to assess smoking and provide cessation support after delivery.

MARIJUANA

Prevalence and Pharmacology

Marijuana is the most widely used illegal drug in the United States, with about 41% of the population reporting trying marijuana at least once. According to the 2007 National Survey on Drug Use and Health (NSDUH) 14.4 million people in the United States are current marijuana users. Marijuana use is most prevalent in young adults, affecting many women of childbearing age. In the 1992 National Pregnancy and Health Survey, it was estimated that 2.9% of women used marijuana during pregnancy. The 2007 NSDUH documented 3.8% of pregnant women used marijuana during the last month. Self-reports are most likely underestimates because the prevalence of marijuana use by pregnant women from specific medical centers and geographic regions have ranged from 4% to 27%, and it is clear that use of biomarkers confirms higher rates of use.

Marijuana, dried material from the hemp plant *Cannabis sativa*, is most often smoked in a cigarette or pipe, although it is highly soluble in lipids and can be administered orally with food. When smoked, it passes more rapidly into the bloodstream through the lungs, resulting in a rapid high lasting up to 3 hours. Of the more than 60 known cannabinoids in marijuana, delta-9-tetrahydrocannabinol (THC) is the primary psychoactive agent. THC binds to cannabinoid receptors (CB1) heavily concentrated in the hippocampus, cortex, cerebellum, nucleus accumbens, and basal ganglia regions of the brain, exerting influence primarily by modifying the release of several neurotransmitters. In addition to euphoria and relaxation, users experience an increase in heart rate by as much as 50% within minutes of administration; blood pressure may also be increased when in a seated or supine position, although hypotension sometimes occurs on standing. Other acute effects include dizziness, reduced salivation, increased appetite, impaired coordination, poor decision making, delayed responding, altered sense of time, and impaired short-term memory, concentration, and learning. Chronic marijuana use in adults has been associated with a number of health complications, including respiratory difficulties and increased risk for lung, head, and neck cancers, as well as increased mental health difficulties such as depression and anxiety and poor achievement.

Fetal and Neonatal Effects

THC crosses the placenta easily and is contained in the amniotic fluid. Because of its high lipid solubility and slow rate of elimination from the body, THC from a single administration may remain in the mother's body for weeks, with potential prolonged exposure of the infant. Cannabinoid receptors are found in the fetal brain early in gestation, suggesting their importance related to brain development. In animal models, administration of THC (or synthetic agonists) during the prenatal and early postnatal periods produced changes in neurotransmitter systems.[63] Modification of neurotransmitters (e.g., serotonin, dopamine, and GABA) may lead to alterations in neuronal growth, maturation, or differentiation, causing structural or functional abnormalities in the fetal brain exposed to marijuana, depending on dose and timing. Because the development and organization of the brain continue after birth, persistent exposure to THC through passive smoke inhalation and breast milk may further influence neonatal outcome and long-term functioning. Indirectly, regular marijuana smoking during pregnancy may reduce oxygen availability to the fetus as a result of high blood levels of carbon monoxide and impaired lung function in the mother.

Despite the potential for unfavorable outcomes in infancy and beyond, relatively little attention has been given to the short- and long-term effects of prenatal marijuana exposure on the child in comparison with other illegal drugs. In general, the impact of in utero marijuana exposure appears to be subtle, and adverse outcomes are more often associated with heavy or more frequent use. Significant pregnancy and delivery complications in relation to marijuana use have not been well documented, and research has not supported an increased risk for major physical anomalies or infant mortality associated with marijuana exposure.[62,70] Although prenatal marijuana exposure has been linked with shorter gestational age, most studies have not confirmed this relationship. Similarly, certain studies report lower birthweight and birth length in marijuana-exposed infants; others indicate no impact on fetal growth.[10,57,62,70]

Neurobehavioral and Developmental Effects

Marijuana-associated neurobehavioral abnormalities such as tremors, startle, and diminished visual response to light stimulus have been noted during the first weeks of life.[69] Additionally, exposed infants have shown sleep disturbances that persist into early childhood.[45] Prenatal marijuana exposure, on the whole, has not been linked to significant developmental delays during infancy,[70] although one study reported lower mental scores at 9 months with daily exposure during the third trimester.[125]

Reports of long-term outcomes related to prenatal marijuana exposure have emerged primarily from two large ongoing research projects, the OPPS and the Maternal Health Practices and Child Development (MHPCD) Study. Data have not generally supported marijuana-related decrements in global indicators of cognitive functioning. However, beginning in the preschool period, exposed children have shown deficits in specific neurocognitive domains. Lower verbal scores were found at age 3 and 6 in the MHPCD study[75] and at age 4 years in the OPPS.[70] As summarized by Fried and Smith,[70] marijuana-associated deficits in aspects of executive functioning, including memory, visual reasoning skills, and planning, have been consistently reported through mid-adolescence. Moreover, marijuana-exposed children show attention and Impulse control difficulties on continuous performance tasks and on questionnaires completed by parents and teachers. Parent and teacher reports also reveal greater hyperactivity and conduct problems in these children. Child ratings indicate higher levels of depression in exposed children compared with controls.[77] Prenatal marijuana exposure may also confer risk for earlier onset and more frequent use of cigarettes and marijuana during adolescence.[47,123]

OPIOIDS

Considerable attention has been paid in the obstetric and neonatal literature to the repercussions on the fetus from maternal heroin use and opioid replacement with methadone or buprenorphine. Although in utero opioid exposure is less common than exposure to other perinatal drugs of abuse, the impact of this class of drugs on the mother and her developing fetus can be profound and life threatening. Opioids (the term represents the family of opiates and opioids) freely cross the placenta to reach the fetus. Morphine is a naturally occurring opiate found in opium poppy. Heroin (diacetylmorphine) is an analogue of morphine that has morphine-like properties by agonist activity at the μ-opioid receptor but is more lipophilic and crosses into the central nervous system (CNS) more rapidly. Heroin has a short half-life (15 to 30 minutes) and when used by pregnant women, readily crosses the placenta, thereby exposing the fetus. Methadone (6-dimethylamino-4,4-diphenyl-3-heptone) is a synthetic opioid used for treatment of heroin addiction because it selectively binds to the μ-opioid receptor and has a longer half-life than heroin.

In addition to being highly addictive, heroin injected intravenously intensifies the risks to the mother and her fetus through potential overdose, acute bacterial endocarditis, and serious viral infections, such as hepatitis B and C and HIV/AIDS. Heroin is also available in forms that can be snorted or smoked, making the drug even more attractive to addicts who may be wary of intravenous use, but the lifestyle and environment of many heroin addicts nonetheless facilitate contraction of sexually transmitted diseases. Prenatal risks also include extrauterine pregnancies due to salpingo-oophoritis, premature labor, premature rupture of membranes, uterine irritability, breech presentation, antepartum hemorrhage, toxemia, anemia, bacterial infections, stillbirth, and low birthweight. Infants exposed prenatally to opioids have less than the expected incidence of respiratory distress syndrome, presumably because of stress-induced accelerated lung maturation with an accelerated production of surfactant; this has been confirmed in animal models.[155] They also have less severe hyperbilirubinemia, which may result from induction of the glucuronyl transferase enzyme system by heroin. Thrombocytosis and increased circulating platelet aggregates have been noted in opioid-exposed neonates. Abnormal thyroid function, manifested by increased triiodothyronine and thyroxine levels, has been described in neonates of methadone-treated mothers. Mothers who use heroin are subject to rapid fluctuations in opioid concentration, and thus the fetus also experiences intense surges and intermittent withdrawal effects.

Increased diversion and illicit use of prescription pain killers, specifically synthetic opioids such as oxycodone, hydrocodone, and codeine, have been reported in Appalachia and rural New England as well as other regions of the nation. As with heroin and other opioids, use of these drugs during pregnancy can lead to drug dependence and overdose, endangering the life of the mother as well as her fetus. After delivery, the infant is at increased risk for withdrawal signs, which may be severe enough to require pharmacologic intervention.

Methadone has been endorsed by a National Institutes of Health Consensus Panel as the standard of care for pregnant opioid-dependent women, based on more than 30 years of experience with methadone maintenance in pregnancy. Methadone has the advantage of a longer-lasting effect, thus lessening maternal and fetal harm compared with heroin, but methadone itself is associated with neonatal withdrawal signs, particularly at higher dosage levels. Still unresolved is the controversy regarding the efficacy and safety of low versus high methadone dosing during pregnancy. The Center for Substance Abuse Treatment Consensus Panel addresses this concern by concluding that the "most effective dose" of maternal methadone maintenance is one that is "individually determined" and "adequate to prevent withdrawal" in the mother.[33] Some investigators advocate maintaining pregnant women on low methadone doses to reduce or eliminate neonatal abstinence syndrome (NAS), whereas others have emphasized that low-dose strategies may increase maternal and fetal risk because they are related to increased maternal withdrawal signs, emergence of drug craving, and failure to curtail illicit drug use. A retrospective review of 21 published studies on maternal methadone dosage (<80 mg versus ≥80 mg daily) and neonatal withdrawal concluded that "the maternal methadone dose does not correlate with neonatal withdrawal; therefore maternal benefits of effective methadone dosing are not offset by neonatal harm."[24] In a contrasting study, there was a significant relationship between maternal methadone (<20 mg per day, 20 to 39 mg per day, and ≥40 mg per day) and neonatal abstinence scores, need for treatment of withdrawal in the infants, and duration of hospitalization.[46] Regardless of the strategy employed, methadone maintenance during pregnancy should be monitored closely by an obstetrician experienced in such therapy in collaboration with an addiction specialist and a supportive nursing and social services team. In uncontrolled circumstances, abrupt maternal opiate withdrawal can threaten the fetus, who also experiences withdrawal, potentially suffering hyperactivity, hypoxia, meconium passage, and in utero demise.[124]

Opioid addiction is a significant problem worldwide. Investigations of alternative pharmacotherapeutic agents for opioid substitution are ongoing in an effort to improve treatment efficacy and diminish known side effects associated with methadone maintenance. In 1996, buprenorphine was introduced in France as an opioid substitute, and studies are ongoing in Europe and the United States. An opioid with mixed agonist and antagonist properties, buprenorphine has a high receptor affinity and a low intrinsic activity compared with other opioids and in adults evokes fewer autonomic signs and symptoms of opioid withdrawal following abrupt withdrawal. Theoretically, therefore, the effects of buprenorphine opioid substitution in pregnancy should be less deleterious to the mother and her fetus. Investigators reviewing published studies found that among infants exposed in utero to buprenorphine (15 cohorts, 309 exposed), NAS was present in 62%, of whom 48% required treatment.[85] Buprenorphine-associated NAS started within 12 to 48 hours, peaked at 72 to 96 hours, and lasted 120 to 168 hours, and it appeared to be "similar to or less than that observed following methadone exposure." In an uncontrolled investigation comparing buprenorphine-maintained and methadone-exposed pregnancies in Sweden, significant advantages were attributed to buprenorphine in terms of infant gestational age and birthweight, incidence and severity of NAS, and duration of hospital stay.[87] Definitive recommendations regarding the use of buprenorphine in pregnancy await the results of well-controlled randomized trials.[86]

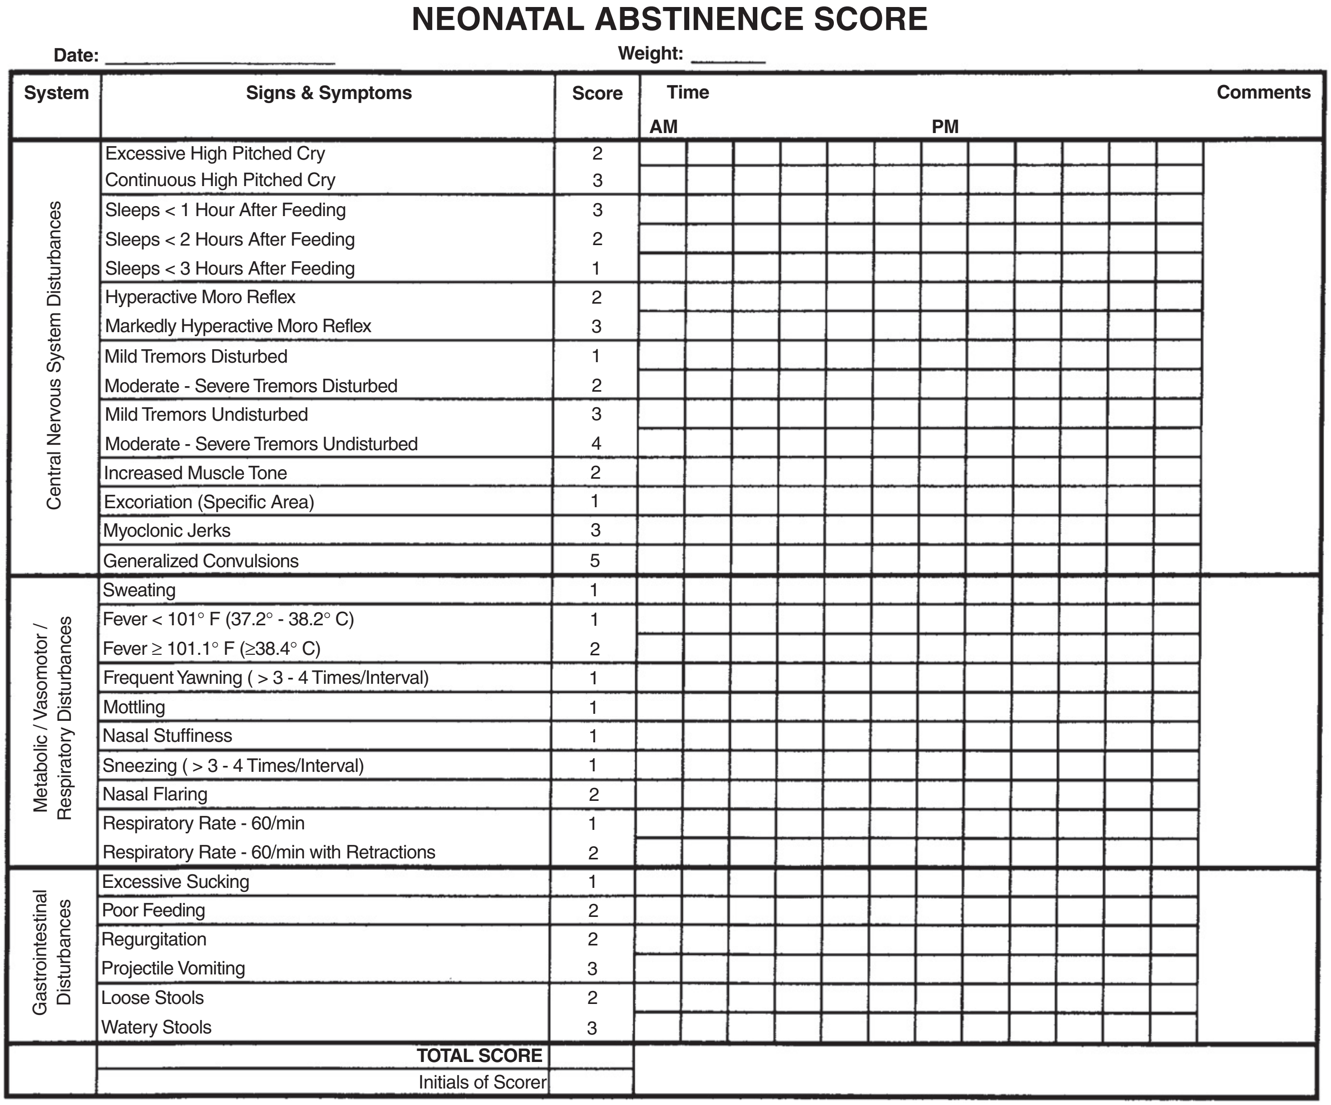
Neonatal Abstinence Syndrome

Neither the animal nor human literature has shown reproducible evidence that in utero opiate exposure causes congenital malformations. The most significant postnatal manifestation of in utero opiate exposure occurs when the fetus is subjected to an extrauterine environment devoid of the exogenous supply of opiates on which the fetal bodily systems have become dependent, and signs of withdrawal ensue. Signs of abstinence occur in 60% to 80% of infants exposed to heroin or methadone. Depending on the pattern of use and the timing of last use, the onset of neonatal withdrawal from narcotics generally begins in the first 2 to 3 days after birth but may occur as late as 4 weeks. Clinical signs associated with NAS encompass effects in the CNS, gastrointestinal system, metabolic system, and autonomic system. The most dramatically affected infants are extremely difficult to console, crying incessantly in a high pitch, spending an inordinate amount of time awake, and exhibiting a hyperactive Moro reflex, hypertonicity, tremors, myoclonic jerks, hyperpyrexia, respiratory distress, vomiting, and watery stools. Sleep deprivation, disorganization, and fragmentation have also been associated with NAS. Seizures are observed in about 2% to 11% of cases. The seizures are easily controlled with anticonvulsant therapy, but other potential etiologies, such as infections, metabolic abnormalities, CNS hemorrhage, or ischemia, should be considered in the differential diagnosis. Before embarking on pharmacotherapy for NAS, the differential diagnosis of withdrawal in a newborn prenatally exposed to an opioid should include such conditions as hypoglycemia, hypocalcemia, hypomagnesemia, sepsis, and meningitis. Because many infants with mild NAS require only supportive care, the clinician's decision to treat with pharmacotherapy should be based on surveillance with serial scoring of withdrawal signs. Two scoring tools are in widespread use in clinical settings as well as research studies—the Lipsitz scale[102] and the Finnegan scale.[64] The Lipsitz scale includes a 0 to 3 rating of each of 11 signs, and a score greater than 4 has been shown to have a 77% sensitivity for detecting significant withdrawal. The more comprehensive Finnegan scale, first used at Thomas Jefferson Hospital at the University of Pennsylvania, requires a trained observer. A modified Finnegan scale scoring system is shown in Figure 38-13. Infants should be initially scored at first appearance of NAS symptoms and then every 3 to 4 hours, based on feeding times. Pharmacotherapy is recommended when scores average 8 or higher over three scoring intervals, or 12 or higher over two scoring intervals. The goal of treatment is decreased irritability, feeding tolerance without vomiting or diarrhea, and sleeping between feedings without undue sedation. Currently available scoring systems were not designed specifically for premature infants, who have been reported to be at lower risk for neonatal abstinence syndrome, perhaps because of CNS immaturity. However, pharmacotherapy for withdrawal in a sick preterm infant born to an opiate-addicted mother should be considered when the infant has signs suggestive of NAS and fails to improve on conventional therapies.

Supportive care for NAS, provided alone or with pharmacotherapy, consists of providing a quiet, dimly lit environment free from noxious stimuli. Loose but effective swaddling may also be an adjunct in the supportive care of NAS, but appropriate adherence to supine positioning should be emphasized, as recommended by the latest Task Force on Sudden Infant Death Syndrome.[90] Neonates exposed to opiates in utero have been reported to have a higher rate of sudden infant death,[89] although this has not been uniformly supported by all investigations. Anoxia in utero may be one plausible mechanism for the observation of SIDS in opioid-exposed infants. In infants who require pharmacotherapy for opioid-induced NAS, opioid substitution should be considered first-line treatment because it provides receptor-specific therapy. A recent survey showed that use of formal scoring systems and therapies for NAS varies widely among NICUs.[132] Recommended by the AAP and frequently prescribed as pharmacotherapy for NAS associated with opioid withdrawal is substitution therapy with morphine in the form of diluted tincture of opium (DTO), a carefully prepared and labeled 25-fold dilution of the 10 mg/mL solution to render 0.4 mg/mL of morphine equivalent.[3] The recommended dosing schedule is a starting dose of 0.1 mL/kg (2 drops/kg) with feedings every 4 hours, with incremental dosage increases of 2 drops/kg every 3 to 4 hours as needed for control of withdrawal signs. After stabilization for 3 to 5 days, the dosage may be tapered gradually without altering dosing interval. Although paregoric (camphorated tincture of opium containing 0.4 mg/mL morphine equivalent) was once recommended, the current recommendation is to treat initially with the diluted tincture of opium rather than paregoric because of the latter's potentially deleterious additives such as camphor, ethanol, benzoic acid, glycerin, and isoquinolones. Some clinicians and researchers advocate morphine or methadone instead of DTO as pharmacotherapy for opiate-induced NAS to avoid the unwanted alcoholic extracts of various alkaloids in the opium tincture.

Phenobarbital has received much investigative attention in studies of infants with NAS. Phenobarbital is not the first-line drug of choice for neonatal opioid withdrawal, but it is recommended for anticonvulsant therapy and for NAS induced by sedatives or hypnotics. NAS is a term generally applied to neonatal withdrawal from heroin, methadone, or other opioids, but similar signs are also seen in withdrawal from other substances, such as alcohol, benzodiazepines, and barbiturates. Phenobarbital may also be administered as a second-line drug for NAS when opioid substitution fails to alleviate withdrawal signs in a newborn born to an opiate-addicted mother. Furthermore, a small prospective, masked, placebo-controlled trial of term infants with NAS (Finnegan score of 8 or higher) comparing DTO alone with DTO plus phenobarbital showed that the combination therapy resulted in less severe withdrawal, shorter mean duration of hospital stay, and reduced hospital cost. However, as the authors suggested, a larger clinical trial with long-term follow-up is needed to confirm that combined DTO plus phenobarbital is indeed optimal pharmacotherapy for NAS.[44]

Other drugs, such as clonidine, chlorpromazine, and diazepam, are not recommended at this time because of insufficient data to support their efficacy or concern regarding potential adverse effects. Naloxone is contraindicated in opioid-exposed neonates because it may induce acute abstinence or seizures. Methadone is excreted in small quantities in breast milk and thus, in the absence of other contraindications (e.g., HIV, use of other illicit drugs) and in clinically



NEONATAL ABSTINENCE SCORE

Date: ______________________ Weight: _______

Figure 38–13. Neonatal abstinence score used for the assessment of infants undergoing neonatal abstinence. Evaluator should check sign or symptom observed at various time intervals. Add scores for total at each evaluation. *(Adapted from Finnegan LP, Kaltenbach K: The assessment and management of neonatal abstinence syndrome. In Hoekelman RA, et al, editors:* Primary pediatric care, *3rd ed, St. Louis, 1992, Mosby, p 1367.)*

monitored cases, breast feeding by the methadone-maintained mother may be cautiously permitted to enhance maternal-infant bonding.

Fetal Growth Effects

There is general consensus that neonates born to heroin-addicted mothers have lower mean birthweight, length, and head circumference than unexposed neonates. This detrimental effect on fetal growth has also been shown in experimental animal models of prenatal heroin exposure. Women in methadone maintenance also have babies with lower birthweights than matched unexposed controls, but their babies have significantly higher birthweights than babies whose mothers use heroin and were not maintained on methadone.[88] Methadone treatment and improved obstetric attention appear to improve fetal growth, resulting in higher birthweights compared with heroin-exposed infants.

Central Nervous System Effects

Gestational exposure to opioids decreases nucleic acid synthesis and protein production in fetal brain and impairs growth of neurons.[106] Rat pups exposed to morphine in utero have changes in the packing density and morphology of neurons and neuronal processes that are significantly smaller than seen with controls. Prenatal opioid exposure has been shown to decrease exploratory behavior and to increase response latency to noxious stimuli in young animals. Furthermore, gestational exposure to morphine also increases self-administration of both heroin and cocaine in adult animals. In preclinical studies in mice, Slotkin and colleagues observed that prenatal heroin exposure evokes neurochemical and behavioral deficits associated with specific interference with hippocampal cholinergic function.[143] In addition, heroin alters elements of cell signaling cascades shared by cholinergic inputs and other neurotransmitter systems. Furthermore, significant deficits in norepinephrine and dopamine turnover that were not seen in the immediate postnatal period emerged later in young adulthood, when hippocampus and cerebral cortex showed almost complete inactivation of noradrenergic and dopaminergic tonic activity. Because methadone, in contrast to heroin, does not produce enduring alterations in norepinephrine or dopamine turnover, the authors speculate that this may have favorable implications for infants born to mothers taking methadone as an opioid substitution for heroin.

Neurodevelopmental Effects

Clinical studies of infant neurodevelopmental outcome following prenatal heroin and methadone exposure are difficult to interpret because of the exposure to both agents and the difficulty with ascertaining adequate control groups and covariate control of other factors that may contribute to outcome, such as genetic factors, exposure to other teratogens, pregnancy and parturition complications, low socioeconomic status, and issues affecting the family and caregiving environment (e.g., drug and alcohol abuse by the mother or other adult household members, domestic violence, maternal HIV/AIDS). Mothers who enter methadone maintenance programs do so because they are addicted to heroin and affected by its multiple accompanying risk factors. Furthermore, many mothers continue to supplement methadone with street heroin as well as alcohol, cigarettes, cocaine, and other drugs. Also complicating the picture is the diversity among practitioners regarding methadone dosing practices. Because heroin abuse in pregnancy is a rather low-incidence disease, the available single-site studies of heroin addiction and methadone treatment in pregnancy have tended to be relatively small, limiting statistical power and generalizability.

Nevertheless, follow-up reports shed light on the potential impact of opioid exposure on human infants and children. In a detailed review of infant and toddler outcomes, several controlled studies have shown various neurobehavioral deficits in infants exposed to methadone in utero, compared with various control groups, using the BNBAS and neurologic assessments.[58] Findings included depressed interactive behaviors; decreased visual and auditory orientation and motor maturity; more jerkiness, tremulousness, hypertonicity, increased arousal, and irritability, and poorer quality of cuddling; and significant mean duration of crying. In a study of videotaped feeding and play interactions, poorer interaction ratings were observed in the methadone-exposed mothers and infants.[84] In unstructured free play at 18 months, methadone-exposed children were noted to have less age-appropriate play—specifically, less time was spent in symbolic pretend play.[114]

Follow-up studies of methadone-exposed infants using the Bayley Scales of Infant Development (BSID) and neurologic examinations have shown motor tone difficulties and transiently lower mean Mental Developmental Index (MDI) and Psychomotor Development Index (PDI) scores. Prenatal opioid exposure was also reported to affect the special sensory organs, leading to an observed increase in otitis media, strabismus, and nystagmus. In a large matched cohort study, there were no significant associations, after covariate control, between in utero opiate exposure and mental, psychomotor, or behavioral functioning.[113] According to Bernstein and Hans, cumulative risk factors predict poorer outcome better than the prenatal exposure to methadone alone.[25] In an investigation comparing children who were born to heroin-dependent mothers and adopted at a very young age, with those born to heroin-dependent mothers (or fathers) but raised at home, the effect of home environment was determined to be more important than in utero exposure.[121]

COCAINE

Prevalence

Few perinatal substances of abuse have engendered as much controversy as cocaine and crack cocaine. Well established in adults is cocaine's propensity for causing severe CNS and cardiovascular toxicity, including convulsions, myocardial infarction, and death. Cocaine ($C_{17}H_{21}NO_4$, benzoylmethylecgonine), an alkaloid derived from *Erythroxylon coca* shrub leaves, is classified as a stimulant. Cocaine hydrochloride, typically snorted as a powder, can also be ingested orally or administered intravenously. Smoking of crack cocaine, an inexpensive alkaloid free-base form of nearly pure cocaine, became widespread in the 1980s, reaching epidemic proportions in many of the nation's inner cities and affecting large numbers of women of childbearing age. Hospitals providing obstetric and newborn services inevitably felt the impact of rising numbers of cocaine-exposed infants. Initially confined to the high-intensity, drug-trafficking areas, this epidemic subsequently spread to remote rural areas. Media attention became focused dramatically on the fate of so-called crack babies. The scientific community, recognizing the challenges of evaluating the effects of in utero cocaine exposure on the developing infant and child, responded with ongoing well-designed prospective longitudinal investigations, which have yielded numerous reports of outcomes within multiple domains of development from birth through early adolescence.

The 1992 NIDA National Pregnancy and Health Survey of drug use by pregnant women showed that 1.1% (about 45,100 U.S. births) had been exposed to cocaine during pregnancy. The 2007 NSDUH showed that 0.4% of pregnant women reported some form of past-month cocaine use, in contrast to 1% of nonpregnant women. Regional differences exist, and cocaine use during pregnancy within some hospitals is substantially higher, as shown in investigations using systematic prenatal or postpartum interviews and bioassays.

Pharmacologic Effects of Cocaine

The main effects of cocaine involve the norepinephrine, dopamine, and serotonin neurotransmitter systems. Inhibition of norepinephrine reuptake leads to accumulation on the synaptic cleft and stimulation of postsynaptic norepinephrine receptors, with manifestations of tachycardia, arrhythmias, hypertension, vasoconstriction, diaphoresis, and mild tremors. Blocking of dopamine reuptake results in dopamine accumulation in the synaptic cleft and stimulation of dopamine neurotransmission, causing neurochemical magnification of the pleasure response, increased alertness, enhanced sense of well-being and self-esteem, and heightened energy and sexual excitement. Compulsive abusers experience anxiety, depression, and exhaustion, and chronic users may exhibit mood disorders, paranoid psychosis, sexual dysfunction, and addiction. Acute tolerance, rebound depression, crash, and craving are explained by regulatory changes in presynaptic and postsynaptic dopaminergic receptors after chronic cocaine use. Cocaine diminishes the need for sleep by decreasing serotonin biosynthesis as a result of decreased uptake of tryptophan.

Cocaine readily traverses the placenta and is also excreted in breast milk. Metabolism of cocaine is primarily through plasma and hepatic cholinesterases to inactive compounds, ecgonine methyl ester and benzoylecgonine, excreted renally. Demethylation of cocaine yields norcocaine, an active metabolite with a greater capacity to inhibit norepinephrine uptake. In pregnant women, fetuses, and infants, plasma cholinesterase activity is diminished, and excretion may be prolonged. Individual susceptibility to cocaine's effects may be related to genetic polymorphism for the cholinesterase enzyme, and the term placenta may also provide a degree of protection for individual fetuses by converting cocaine into less active metabolites, presumably by cholinesterase activity.

Cocaine use during pregnancy alters fetal oxygenation by reducing uterine and placental blood flow and impairing fetal oxygen transfer. Fetal tachycardia and hypertension reflect fetal hypoxemia, or increased fetal levels of cocaine or fetal catecholamines, or a combination. In animal studies, significant increases in maternal and fetal arterial pressure and decreases in uterine blood flow have been reported. In humans, maternal and fetal deaths have been linked to cocaine use, and pregnant cocaine-abusing women are at increased risk for spontaneous abortions, abruptio placentae, and premature rupture of the membranes. Transient neonatal ventricular tachycardia has been associated with maternal cocaine abuse shortly before delivery. Higher arterial blood pressure and diminished cardiac output and stroke volume, presumably affected by increased norepinephrine levels, have also been reported in full-term cocaine-exposed infants compared with drug-free infants on the first postnatal day.

There is no definitive dysmorphology syndrome (such as FAS) associated with prenatal cocaine exposure. In animal studies of gestational cocaine exposure, a wide variety of congenital anomalies, including exencephaly, anophthalmia, malformed or missing lenses, cryptorchidism, hydronephrosis, grossly distended bladder, limb reduction defects, ileal atresia, and cardiovascular anomalies, have been described. It has been hypothesized that cocaine-induced blockage of norepinephrine uptake is responsible for placental vasoconstriction and fetal hypoxia, which produce the defects. Cocaine has also been determined to be teratogenic in a dose-dependent manner during late organogenesis or during the postorganogenic period in the Sprague-Dawley rat. The observed pattern of defects, principally reduction deformities of the limbs and tail and genital tubercle defects, occurred as a result of hemorrhagic necrosis, disruption, and amputation of existing and developing structures.[161] An important concept is that vulnerability to cocaine-induced structural defects may not be limited to the period of organogenesis but instead may be related to aberrations in fetal, placental, and uterine blood flow leading to fetal vascular disruption—that is, a structural defect may result from destruction of a previously formed, normal part.

The structural defects described in the animal studies mirror those from human case reports and small series, especially observations from referral services such as neurology, cardiology, and nephrology-urology. However, most infants exposed prenatally to cocaine are born without defects, and systematic investigations have failed to show a discernible pattern or an increased prevalence of congenital malformations associated with gestational cocaine exposure in humans, with the possible exception of genitourinary tract defects.[20] Cocaine-induced ischemia may play a role in the development of intestinal atresia, infarction, and necrotizing enterocolitis, which has been observed in term and preterm infants prenatally exposed to cocaine.

HIV/AIDS and Sexually Transmitted Diseases

Cocaine-using women are more prone to a variety of sexually transmitted diseases both before and during pregnancy. Intravenous substance abuse by the woman or her sexual partner is a recognized HIV risk factor, but sexual promiscuity and trading of sex for cocaine or crack also increases the risk for heterosexual transmission of HIV infection and other sexually transmitted diseases in cocaine-abusing women of childbearing age. These infections occurring in pregnancy pose additional risks to the fetus.

Prematurity

Although an increased rate of premature delivery or a shorter gestation has been reported in cocaine-using women, this finding is not consistent across studies. Prenatal cocaine exposure has been associated with shorter gestational age even in women receiving prenatal care.[16,128] In larger samples, observed differences in gestational age between cocaine-exposed and unexposed infants, although perhaps statistically significant, have been modest (i.e., about 1 week or less).[12,16]

Intrauterine and Postnatal Growth

The most frequently reported adverse consequence of prenatal cocaine exposure is intrauterine growth restriction. Studies in Long-Evans rats have shown that prenatal cocaine exposure results in dose-dependent decreases in birthweight and postnatal growth and alterations in fetal body composition, with lower levels of body fat, protein, and calcium.[35] In humans, restricted intrauterine growth may be in part the result of malnutrition and poor weight gain in the mother because of cocaine's suppression of appetite, but in utero cocaine exposure appears to result in depressed neonatal fat stores and diminished lean body mass, even after controlling for maternal weight gain.[67] Structural equation modeling revealed a direct impact of prenatal cocaine exposure in term infants on fetal growth involving birthweight, length, and head circumference in the large single-site Miami Prenatal

Cocaine Study cohort of cocaine-exposed compared with unexposed term infants, after control of potential confounders.[12] From the Maternal Lifestyles Study, which includes cohorts from a multi-site study of term and preterm infants, there is evidence that the impact of prenatal cocaine exposure on fetal growth may be more pronounced later in gestation, with a cocaine-associated deceleration in growth occurring after 32 weeks' gestation.[9] Other prospective clinical investigations of in utero cocaine exposure have reported somewhat inconsistent results, with some confirming cocaine-associated decreases in one or more anthropometric measures and others reporting no differences, especially after adjustment for selected covariates. Furthermore, higher cocaine levels in maternal hair have been correlated with lower head circumference, suggesting a significant dose-response effect.[15] In a unique rural longitudinal prospective cohort on prenatally cocaine-exposed and unexposed infants, Behnke and colleagues highlighted the potential significance of this finding in their report of indirect effects of prenatal cocaine-associated birth head circumference decrement on preschool development.[21]

Data on long-term growth of prenatally cocaine-exposed children are sparse, and cross-sectional and longitudinal findings also vary from cohort to cohort and by specifically affected growth parameters. One investigation reported that cocaine-exposed children, particularly those born to older mothers, were shorter and more likely to have clinically significant height deficits at age 7 years.[43] In a longitudinal growth curve analysis of growth from 1 to 10 years, prenatal cocaine exposure during the first trimester was related to a slower rate of growth in both weight and head circumference over time.[126] In contrast, another investigation showed that the cocaine-exposed children experienced catch-up growth, mainly in the first 6 to 12 months, that resulted in no apparent deficits in height, weight, or head circumference by age 8 years.[104] As has been suggested with prenatal tobacco exposure, early infancy catch-up growth in response to prenatal cocaine exposure may prove to be a risk factor for obesity in later childhood and adolescence.

Sudden Infant Death Syndrome

Like tobacco and opioids, cocaine has been previously linked to SIDS. However, a meta-analysis concluded that an increased risk for SIDS could not be attributed to intrauterine cocaine exposure alone, after controlling for concurrent use of other drugs.[60]

Central Nervous System Effects

Cocaine adversely affects CNS development by binding with monoaminergic receptors in the fetal brain. Animal studies have demonstrated altered neocortical development, including inappropriate placement of neurons, deficient lamination, and decreased volume, density, and total number of neocortical neurons, after prenatal administration of cocaine, and some of these abnormalities persist beyond the newborn period. Additionally, prenatal cocaine exposure has been shown to produce functional changes in the dopaminergic and serotonergic systems in offspring. Moreover, observed structural and functional alterations have been associated with neurobehavioral abnormalities in animals (e.g., attention, learning) that closely parallel findings in clinical studies.[101,109] Investigations in neonatal rats exposed prenatally to cocaine have shown significant neurobehavioral deficits, including hyperactivity, abnormal sexual behavior (demasculinization) in adulthood, and significantly increased metabolic activity of the limbic, motor, and sensory system of female, but not male, rat brains, as reviewed by Hutchings and Dow-Edwards.[81]

Cocaine-induced alterations in cerebral blood flow have been implicated in CNS hemorrhagic and ischemic lesions. Concern, raised initially by a single case report of a cocaine-exposed term infant with neonatal cerebral infarction, was heightened by a larger series of full-term infants exposed to cocaine, amphetamines, or both, who were reported to have echoencephalographic evidence of white-matter cavities, acute infarction, intraventricular hemorrhage, subarachnoid hemorrhage, and ventricular enlargement.[51] However, a subsequent well-controlled prospective study of mainly full-term infants did not substantiate an increased risk for CNS structural lesions associated with prenatal cocaine exposure.[19] In another well-designed study of full-term and near-term infants, no group differences were noted between cocaine and comparison groups, but subependymal hemorrhages were found more frequently among more heavily cocaine-exposed compared with unexposed infants.[68] With regard to prematurity, known to be associated with intraventricular hemorrhage and periventricular leukomalacia, a relatively large study of premature infants with very low birthweight showed no group differences in the rate of these complications between cocaine-exposed and unexposed infants.[53]

In human infants with in utero cocaine exposure, neonatal electroencephalographic abnormalities, clinical seizures that may extend beyond the perinatal period, and aberrations in auditory brainstem response have also been noted.

Infant and Toddler Neurobehavior and Mental and Psychomotor Development

Infant neurobehavioral functioning, measured by the Brazelton Neonatal Behavioral Assessment Scale (BNBAS), the NICU Network Neurobehavioral Scale, and other measures, has been a primary focus of nearly all of the prospective longitudinal cohort studies of in utero cocaine exposure. On the BNBAS, poorer state regulation, impaired autonomic control, irritability, poorer orientation, decreased habituation, diminished alertness, and abnormal reflexes, tone, and motor maturity have been reported among cocaine-exposed infants, although there has been little consistency across studies in the specific domains affected. Meta-analysis indicated reliable but modest cocaine-associated effect sizes for the motor and abnormal reflex clusters of the BNBAS.[78] In a large cohort of full-term infants, prenatal cocaine exposure was modestly related to all BNBAS domains except abnormal reflexes, even with statistical control for other drug exposures and key infant and maternal characteristics.[116] Several controlled studies with large sample sizes detected no cocaine-associated deficits on the BNBAS at birth, but two of these studies reported abnormalities in areas such as state regulation, autonomic regulation, and reflexes at 2 to 4 weeks postpartum.[38,158] Prenatal cocaine exposure was related to lower arousal, lower regulation, and high excitability on the NICU Network Neurobehavioral Scale at 1 month of age after adjustment for pertinent covariates.[98] Prenatal cocaine exposure also has been associated with an increased number of cry utterances and short cries, suggestive of an overaroused (excitable) pattern of neurobehavioral functioning.[42,98] Other neurologic and physiologic measures have also revealed neurobehavioral abnormalities such as increased jitteriness, irritability, and poorer auditory response and habituation among cocaine-exposed infants. Moreover, cocaine-associated alterations in physiologic regulation during infancy using measures of heart rate and respiratory sinus arrhythmia have been reported.[134] A dose-response effect has been documented, with poorer neurobehavioral functioning found in infants exposed to higher or more frequent doses of cocaine prenatally.[59,134,158] Although these early neurobehavioral abnormalities do not appear to be related to cocaine intoxication or withdrawal symptoms, it is not yet known to what degree they will persist beyond infancy. Recent studies suggest that these early neurobehavioral impairments may endure because cocaine-exposed children have been shown to display greater reactivity and poorer regulation during stressful conditions later in infancy and in the preschool years.[50,54]

Numerous published studies have examined the effects of prenatal cocaine exposure on early cognitive and motor development. Prenatal cocaine exposure has been associated with lower MDI scores on the BSID during the infant and toddler years in some studies. Compared with unexposed children, children with gestational cocaine exposure were more likely to score in the delayed range and to show a more significant decline in MDI from 6 to 24 months of age.[139] In another report, prenatal cocaine exposure was associated with lower overall MDI assessed at several time points from 3 to 36 months of age. The observed relationship was mediated by birthweight and gestational age, and the cocaine-exposed children showed a decline in cognitive performance through age 24 months but did not differ from unexposed controls in developmental trajectories.[110] Other studies have not found a relationship between prenatal cocaine exposure and early cognitive development after covariate adjustment.[30,113,127] Most studies report no specific cocaine effect on BSID motor performance.[113,139] In contrast, in longitudinal analyses of motor development, cocaine-exposed compared with unexposed infants demonstrated early deficits in motor development with recovery to normal functioning by 18 months.[115] Several reports highlight the importance of the postnatal caregiving environment in influencing developmental outcome in cocaine-exposed children.[30,113]

Child Cognition, Neurodevelopment, and Behavior

Most published reports on IQ in prenatally cocaine-exposed preschool- and school-aged children document no significant global IQ difference in cocaine-exposed compared with unexposed groups from similar backgrounds. In studies demonstrating cocaine-associated deficits in cognitive functioning, effects are generally subtle, are often mediated or moderated by other variables, and tend to be specific to more specialized domains of function such as perceptual reasoning, visual-motor skills, and memory.[6,22,140] Large, well-controlled investigations have documented a cocaine-specific effect on language-processing abilities through early school years after consideration of other prenatal exposures and other covariates and when considering a dose-response relationship. Studies specifically addressing longitudinal analyses of language found significant prenatal cocaine-associated deficits throughout the period of study during early childhood but no group differences in trajectory of language development over time.[14,100] A recent report from a large cohort study, however, found no main prenatal cocaine exposure effects on standardized language measures at 6 and 9.5 years, although interaction effects included lower receptive scores at age 6 in prenatally cocaine-exposed children, and moderating effects for birthweight and gender.[18] Extant data, although limited, suggest that prenatally cocaine-exposed children do not differ from unexposed peers on standardized tests of achievement or indicators of academic performance, at least through the early school years.[80,140] However, prenatal cocaine exposure has been linked to increased risk for learning disability at age 7 years,[117] and receipt of special education services.[99]

Preclinical studies have associated the effects of cocaine exposure with structural and functional alterations in the monoamine system, involving norepinephrine and serotonin pathways throughout the brain and more targeted dopaminergic circuits.[109] Dopamine depletion has been linked to long-term cocaine exposure in studies of laboratory animals and adult humans. An extensive review of the animal literature notes a consistent pattern of cocaine exposure's direct effects on dopaminergic pathways central to arousal regulation and attentional reactivity in prenatal and preweaning rats.[109] Emerging imaging data with school-aged children have also begun to reveal possible cocaine-associated structural and functional variations in dopamine-rich areas of the brain. Prenatal cocaine exposure has been linked to less mature development of frontal white-matter pathways,[160] reduced caudate volume,[8] and increased frontostriatal activation during a response inhibition task.[138] Clinically, cocaine-exposed children have demonstrated subtle deficits on tests of executive functioning, a largely frontal lobe–mediated process that involves the ability to plan and accomplish future goals or actions and the ability to inhibit or control motor responses that interfere with goal attainment.[108,130,160] Additionally, preschool- and school-aged cocaine-exposed children, when compared with unexposed controls, exhibit impaired attentional processing as measured by omission errors on computerized continuous performance tasks,[13] and evidence greater restlessness, distractibility, and noncompliance as rated by observers in a clinic setting. Some studies indicate increased levels of behavior problems as rated by parents and teachers. As cocaine-exposed children enter later childhood and early adolescence, of particular interest is whether in utero cocaine exposure will influence the child's own drug involvement. Although clinical data are not yet available, increased self-administration of cocaine has been demonstrated in adult rats after in utero cocaine exposure.[129] In addition to neurochemical and vascular mechanisms of prenatal cocaine exposure pathophysiology on fetal development, Lester and Padbury propose a third mechanism in which cocaine may also act as an intrauterine stressor, that is, a challenge that alters the internal milieu of the fetus and disrupts genetic programming of fetal-placental development, consistent with the concept of fetal origin of adult disease.[97] They hypothesize that alterations in hypothalamic-pituitary axis stress responses may underlie long-term behavioral and emotional problems, including compulsive disorders such as drug addiction in prenatally cocaine-exposed offspring.[97]

Early fears of devastating effects of cocaine in vast numbers of affected infants have not been substantiated by systematic prospective studies or meta-analyses. However, reports in individual cases that show the potential for cocaine to be associated with severe anomalies or vascular disruptions may indicate low-incidence cocaine-associated lesions expressed in certain hosts, depending on dosage or pattern of exposure or individual susceptibility factors, such as genetics, metabolism, maternal nutrition, and maternal health conditions.

Large prospective studies have now begun to show converging evidence for significant, albeit relatively subtle, cocaine-associated deficits in a number of domains of neurobehavioral and neuropsychological functioning, such as sustained attention, language functioning, and behavior. In many of the studies, the observed deficits appear to be statistically robust indicators of cocaine exposure because they persist even after controlling for numerous environmental confounding variables. Furthermore, in some studies, the effects have been shown to be dose dependent, which lends credence to a teratologic effect. The importance of cocaine-associated subtle deficits should not be overlooked because they may be costly in terms of increased numbers of children qualifying for special services in the school system.[96]

Significant deficits in executive function may not become apparent until the child reaches late adolescence or young adulthood as complex frontal lobe neurons complete their developmental trajectory of maturation into adulthood. Thus, "sleeper effects" of prenatal cocaine exposure may emerge later to affect real-life functionality as these children face increasing demands related to academics, social situations, and acceptance of responsibility for the well-being of themselves and others.

More attention needs to be paid to gender modification of cocaine effects by addressing the potential for sex-related effects on specific outcomes, even when there are no apparent group differences in the overall sample. Although male-female differences have been reported,[22,49] sex and gender variations in the impact of prenatal cocaine exposure are not well understood.

In clinical populations, the mothers seldom use cocaine as a single agent, and it has become increasingly evident that in studies of the effects of perinatal substance abuse, analyses should include assessment of the effects of drug-drug interactions on the outcomes of interest. Consideration should also be given to the myriad caregiving environmental factors that may influence these results. Addressing these analytic challenges are important in understanding the risk and resiliency factors and cumulative risks that predict individual and group outcomes. A growing number of studies show the contribution of environmental risk (e.g., poverty, caregiver instability, domestic and community violence exposure) in influencing a variety of outcomes in cocaine-exposed children.

Finally, it should be noted that cocaine exposure in infants is not limited to the in utero environment. Cocaine exposure through breast milk has been reported to cause intoxication in the newborn. Postnatal ingestion and passive inhalation of cocaine and crack cocaine have also been reported to cause toxicity in young infants and toddlers, and, of course, active and passive exposure could affect older children and adolescents in high-risk environments.

AMPHETAMINES

In the western part of the hemisphere, abuse of amphetamines and methamphetamines is especially predominant, and many users of amphetamines and methamphetamines are women of childbearing age. Although published data are limited, the obstetric and neonatal complications associated with prenatal exposure to these substances appear to be similar to those observed with cocaine. Amphetamine (methylphenylethylamine) is a stimulant of norepinephrine, dopamine, and serotonin release, and the clinical effects have a longer duration of action than cocaine. Methamphetamine (also known as *meth*, *speed*, *ice*, and *crystal*), is the *N*-methyl homologue of amphetamine. With better blood-brain barrier penetration than amphetamine, methamphetamine has significantly higher CNS stimulant effect and less peripheral nervous system and cardiovascular stimulation. Gestational methamphetamine exposure has been reported to increase the incidence of miscarriage, prematurity, intrauterine growth restriction, and placental hemorrhage. Infant feeding and sleep patterns are disturbed, and hypertonia and tremors have been observed. Little and colleagues, in a retrospective medical record review, showed that infants exposed prenatally to methamphetamine had significantly lower birthweight, length, and head circumference than unexposed control infants.[103] No difference in congenital anomalies was noted. In the large, prospective, longitudinal, multi-site study of the effects of prenatal methamphetamine exposure (the Infant Development, Environment and Lifestyle, or IDEAL, study), methamphetamine exposure was associated with lower birthweight and increased incidence of small for gestational age at delivery.[144] This study also found a dose-response relationship between prenatal methamphetamine exposure and infant neurobehavioral outcomes, with exposed infants demonstrating increased physiologic and CNS stress, lower arousal, and increased lethargy relative to unexposed controls.[145] In one study using magnetic resonance imaging, children (ages 3 to 16 years) with a history of prenatal methamphetamine exposure were found to have smaller subcortical volumes that correlated with poorer performance on cognitive tests of visual-motor integration, sustained attention, and verbal and long-term spatial memory.[34] Although limited by small sample size, this investigation provides preliminary clinical evidence that in utero methamphetamine exposure may have neurotoxic effects on brain development, with possible long-term implications for cognitive and behavioral functioning.

A growing concern related to parental methamphetamine abuse is environmental exposure to methamphetamine and other chemicals in infants and children due to in-home manufacturing of the drug. "Meth labs" have become increasingly popular in certain areas of the United States, and case reports of accidental ingestion in infancy and childhood of methamphetamine and chemicals used in its production have been published.[61,76] Large, systematic studies of children with environmental exposure to methamphetamine are not available, but one initial report suggests greater behavioral problems in children with a history of residing in methamphetamine-producing homes.[7]

Ecstasy, or MDMA (3,4-methylenedioxymethamphetamine), has become increasingly popular as a recreational drug since the late 1980s. MDMA is an indirect monoaminergic agonist that stimulates release and inhibits reuptake of serotonin and other neurotransmitters, thus evoking elation and pleasure, accompanied by undesirable effects of hyperactivity and hyperthermia. Subsequent monoaminergic depletion leads to depression and lethargy. Cardiac arrhythmia, acute renal failure, rhabdomyolysis, disseminated intravascular coagulation, and death have been reported in young people using MDMA and engaging in "rave dancing" at crowded clubs. Corroborated by animal studies, chronic MDMA use by adult humans has been shown to cause long-term neuropsychopharmacologic damage in terms of learning/memory, cognitive function, sleep, appetite, and loss of sexual pleasure. These effects persist even during abstinence, suggesting permanent axonal loss.

Skelton and colleagues recently summarized evidence from a number of preclinical studies that indicates developmental exposure to MDMA is related to persistent learning and memory difficulties in offspring.[141] One study of neonatal rats, postnatal days 11 to 20 (correlating with late third trimester in human brain development), shows that MDMA exposure causes dose-related sequential learning and spatial learning and memory deficits, but these effects are not seen with MDMA exposure at postnatal days 1 to 10 (correlating with first-trimester human brain development). Thus, timing of exposure appears to play a critical role in expression of effects.[29]

A study of ecstasy in humans described the characteristics of pregnant women in Toronto, Canada, who contacted the Hospital for Sick Children's Motherisk Alcohol and Substance Use Hotline and reported ecstasy use during pregnancy.[79] Compared with nonusers, MDMA users were younger and more likely to be white and single. MDMA users were also more likely to smoke cigarettes, drink alcohol, engage in binge drinking, use other illicit drugs, have coexisting psychiatric or emotional problems, and have unplanned pregnancies. Thus, the typical pregnant MDMA user appears to have multiple pregnancy risk factors. The United Kingdom National Teratology Information Service collected follow-up data on 136 ecstasy-exposed pregnancies and found a significantly increased risk for congenital defects, predominantly cardiovascular and musculoskeletal anomalies, in the offspring.[111] The authors acknowledge that although the findings are clearly of interest, the study sample was quite small, with limited power to draw definitive conclusions regarding causality of the observed defects. Published reports of other neonatal and infant outcomes of gestational ecstasy exposure are not yet available. Many of the same caveats cited previously with regard to the interpretation of findings related to prenatal cocaine exposure are applicable to the study of these stimulants as well.

SEROTONIN REUPTAKE INHIBITORS

Although not categorized as abuse substances, there is evidence for increasingly widespread maternal use of selective serotonin reuptake inhibitors (SSRIs) during pregnancy.[163] These drugs are being commonly prescribed as the treatment of choice for major depression and anxiety. Although SSRIs vary in potency, pharmacokinetic effects, molecular structure, and half-life, the SSRIs act similarly by inhibiting serotonin reuptake at the presynaptic junction, leading to increased concentrations at the synaptic cleft and potentiating serotonergic neurotransmission. Thus, the fetus is exposed to increased serotonin levels during development. An early meta-analysis of several smaller studies of SSRI use in the first trimester was reassuring with regard to no demonstrable increased risk for congenital malformations,[93] but subsequently concerns have been raised regarding an observed increase in congenital malformations associated with maternal therapy during pregnancy with SSRIs, especially paroxetine (Paxil).[23] Gestational SSRI exposure has also been implicated in persistent pulmonary hypertension of the newborn, but this observation also requires further substantiation. There is an emerging literature that prenatal SSRI exposure and possibly withdrawal may be associated with neurobehavioral effects that may include changes in behavioral state and altered autonomic reactivity. Whether this actually constitutes a neonatal abstinence syndrome and whether there are long-term developmental consequences of in utero exposure to SSRIs remains unclear. Awaiting more definitive long-term studies of safety, clinicians should carefully consider the maternal diagnosis and indications as well as the potential risks and benefits before prescribing treatment with SSRIs during pregnancy.

SECTION VI

Development and Disorders of Organ Systems

CHAPTER 39

The Immune System

PART 1

Developmental Immunology

Reuben Kapur, Mervin C. Yoder, and Richard A. Polin

Developmental immunology can be defined as the study of how adaptive host defense blood cells in an individual sequentially respond to repetitive environmental challenges in a way that promotes the health and survival of the individual throughout maturation from fetal to adult life. According to classic principles, an individual becomes immune, or protected from reinfection, in response to an antigenic encounter during an initial infection. Mature immunologic competence is ultimately achieved through cumulative adaptive changes stimulated by exposure to a large repertoire of foreign antigenic material. Because the in utero fetal environment is sequestered from frequent encounters with microorganisms, the host defense system of the human newborn is inexperienced. This inexperience partially accounts for why newborns are so vulnerable to microbial attack during the first 6 weeks of life. Although many components of the immune system of the fetus are present early in gestation, some are immature and do not become fully functional (compared with the activity of immune defenses of adult subjects) until some time after birth. Despite these limitations, fetal host defense systems are capable of active engagement, and an immune response does occur when the fetus is infected in utero.

An understanding of the development of the immune system in a particular fetus or neonate must take into account the specific environment in which that individual is developing. Because more prematurely born neonates with very low birthweight are surviving, it is possible to ask how the immunologic development of these infants (in an extrauterine environment) differs from in utero immunologic development of comparably aged fetuses. This chapter reviews the sequential appearance of the many components of the immune system in neonates and compares the functional activities of these components with those of immunologically competent adults.

The immunologic system may be divided into two systems of host defense mechanisms: innate, or nonspecific, immune mechanisms, and acquired, or specific, immune mechanisms. By definition, *innate immunity* includes host defense mechanisms that operate effectively without prior exposure to a microorganism or its antigens. Some of these mechanisms include physical barriers, such as intact skin and mucous membranes, and chemical barriers, such as gastric acid and digestive enzymes. Beneath these important protective layers lie phagocytic cells, which constitute the first line of host defense against any microbes that breach the cutaneous and mucosal barriers. Soluble plasma and tissue proteins serve to amplify the function of the phagocytic cells as innate immune effectors. *Acquired,* or specific, *immunity* comprises primarily the cell-mediated (T lymphocyte) and humoral (B lymphocyte and immunoglobulin) systems.

Innate and acquired immune mechanisms are necessary for an individual to become fully immunocompetent. These systems are intimately interrelated and interdependent. Monocytes and macrophages are important components of natural immunity because these cells function to ingest and clear microbial pathogens from normal tissues. Monocytes and macrophages also play an important role in the processing and presentation of microbial antigenic material to T lymphocytes, a pivotal initiation step in the generation of a specific immune response. Monocytes and macrophages are important components of the innate and the acquired immune systems, and are necessary for an effective immune response.

OVERVIEW OF HEMATOPOIESIS

All the cellular components of the immunologic system have limited life spans; the cells must be constantly replenished from a pool of undifferentiated precursor cells derived from a pluripotent stem cell. Hematopoietic stem cells are capable of self-renewal, ensuring maintenance of a lifelong pool of available hematopoietic precursors. Through mechanisms that are not well understood, pluripotent stem cells are stimulated to divide and differentiate into multipotent stem and committed progenitor cells, which mature into circulating blood cells.[3] Fibroblasts, endothelial cells, and macrophages present in the microenvironment of the hematopoietic stem cells synthesize extracellular matrix molecules and growth factors that are crucial to the process of progenitor-derived blood cell production.

Evidence that mice could be protected from the lethal effects of total-body irradiation by exteriorizing and shielding of the spleen provided some of the first evidence that the hematopoietic system may be maintained through a population of precursor cells. Later, Till and McCulloch[50] showed that marrow withdrawn from a donor animal could repopulate the spleen of a lethally irradiated recipient animal with progenitor cells, giving rise to discrete colonies of red blood cells, megakaryocytes, granulocytes, and macrophages. The pluripotent hematopoietic stem cell was first isolated and characterized in mice. An equivalent cell in humans can be inferred from the successful long-term engraftment and proliferation of donor cells in recipient patients after bone marrow transplantation.

Development of other monoclonal antibodies that recognize cell surface molecules highly expressed by murine and human hematopoietic stem cells has permitted isolation and characterization of the growth and differentiation requirements of this rare hematopoietic cell population. In vitro colony-forming assays have been used to confirm that the proliferation and survival of hematopoietic progenitor cells are maintained by hematopoietic growth factors. Hematopoietic growth factors not only promote production of blood cells, but also enhance the maturation of cells; granulocyte ingestion and killing of invading microbes are stimulated by several hematopoietic growth factors. Hematopoietic growth factors play an important regulatory role in providing adequate numbers of functionally mature blood cells during systemic infections.

Fetal hematopoiesis begins in a primitive state early in gestation, before the development of a mature bone marrow hematopoietic microenvironment. The anatomic location of blood cell production changes several times during gestation as stem cells apparently home from one site to another.[61] Early hematopoietic activity is restricted to the yolk sac until 6 to 8 weeks of gestation, when the liver becomes the predominant site. As gestation proceeds to the 20th week, the bone marrow becomes the major site of hematopoiesis, and thereafter remains the primary reservoir for replenishing circulating populations of immune cells.

INNATE IMMUNITY

Cellular Components

The most primitive host defense mechanism involves the ingestion and killing of bacteria and other microorganisms by phagocytic cells. Polymorphonuclear neutrophils (PMNs), monocytes, and macrophages are the major cell types that accomplish this aspect of host defense. Natural killer (NK) cells are also important components of the innate immune system, but these cells kill invading pathogens by nonphagocytic mechanisms. All these cell types can eliminate pathogens from the host, but do so more efficiently when the pathogens are opsonized, or coated, by complement components and other soluble proteins of the innate immune system. Likewise, the nonphagocytic mechanisms of microbial cytolysis used by NK cells, PMNs, and monocytes are augmented in the presence of specific antibody to the target organism. This section provides an overview of the phagocyte and NK cell systems and highlights the areas in which phagocytes isolated from fetal and neonatal blood seem functionally immature.

POLYMORPHONUCLEAR NEUTROPHIL SYSTEM

Kinetics of Production and Circulation

The PMN system arises from a progenitor cell called the colony-forming unit granulocyte-macrophage (CFU-GM). As the name implies, this stem cell–derived progenitor cell may differentiate into PMNs or monocytes. The myeloblast is the first identifiable neutrophil precursor. Myeloblasts produce many daughter cells (myelocytes). These nonproliferating cells require 7 days to become fully differentiated PMNs. This postmitotic compartment of differentiating but immature PMNs (metamyelocyte and band forms) and mature bone marrow PMNs constitutes a reserve pool of cells that may be rapidly mobilized into the circulation in response to inflammation.

Positive and negative regulators of PMN production have been identified. Positive regulatory factors are interleukin (IL)-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), and granulocyte CSF. Several negative regulators of PMN production have also been identified, including interferons (IFNs), transforming growth factor-α, macrophage inflammatory protein 1a, prostaglandins, and lactoferrin and other iron-binding proteins.

Although it is unclear what factors cause PMN release from the bone marrow under normal conditions, IL-1, tumor necrosis factor–α (TNFα), epinephrine, and complement component fragments are known to stimulate PMN release from the bone marrow during inflammatory states. When mature PMNs leave the marrow environment, they circulate for approximately 6 to 8 hours before migrating into tissues, where they live for an additional 24 hours. While in the bloodstream, half of the PMNs are found in a marginated pool (primarily in the pulmonary capillaries), and half are circulating in the peripheral blood. After PMNs emigrate from the blood vessels and enter a tissue, they do not reenter blood vessels, but age and die in the tissue. The actual site of PMN clearance is unknown, but macrophages ingest and degrade senescent apoptotic PMNs in vitro.

In the human fetus, PMN precursors are first identified in the yolk sac stage of primitive hematopoiesis.[61] Mature PMNs are not identifiable in the fetal liver or bone marrow until approximately 14 weeks of gestation. By 22 to 23 weeks of gestation, the circulating PMN count has increased, but still is only approximately 2% of the circulating PMN concentration measured in the cord blood of term gestation newborns. At the same time that circulating concentrations of PMNs are low, fetal blood contains high concentrations of circulating hematopoietic progenitors. This high concentration of circulating progenitors may not be indicative of a large total body pool of progenitors, however. The actual number of CFU-GMs in the human neonate is unknown. In comparative studies of fetal and neonatal rat hematopoiesis, the total-body CFU-GM pool was approximately 10% by weight of that of adult rats. One explanation for the high concentration of circulating progenitors is that these stem cells may be leaving one hematopoietic environment (the liver) for another (the bone marrow).

Circulating concentrations of PMNs increase dramatically at birth, peak at 12 to 24 hours, and then decline slowly by 72 hours to values that remain stable during the neonatal period. The PMN count rarely decreases to less than 3000/mm^3 during the first 3 days and less than 1500/mm^3 thereafter in term infants, although PMN counts in preterm infants may be 1100/mm^3. When searching for the cause of neutropenia (<1500 PMNs/mm^3) in infants, a strong suspicion of infection is warranted, although infants with preeclamptic mothers, premature birth, birth depression, intraventricular hemorrhage, and Rh hemolytic disease may have low peripheral PMN counts. Persistent neutropenia is one feature that is frequently seen in patients who succumb to overwhelming sepsis. Neutropenia in these infants may occur because of increased margination of activated circulating cells or may be related to rapid depletion of circulating and bone marrow storage pool PMNs. Whatever the mechanism, failure to provide adequate numbers of PMNs to areas of microbial invasion in tissues may be a factor that places the infant at increased risk for development of overwhelming sepsis.[25]

Overview of Polymorphonuclear Neutrophil Functions

The PMN is qualitatively and quantitatively the most effective killing phagocyte of host defense. Numerous coordinated steps are required to attract large numbers of PMNs from the circulating blood into a tissue at the site of microbial invasion (Fig. 39-1). When microorganisms penetrate cutaneous or mucosal barriers, macrophages and PMNs appear in the tissue, and along with the complement, kinin, and coagulation systems, initiate a series of events resulting in the release of complement fragments (particularly C5a) and other factors (IL-1, TNFα, and chemokines) that alter vascular endothelial cell morphology and function in the area of infection.

The initial recognition of invading microbes by the macrophages and PMNs is facilitated by the presence of pattern recognition receptors (Toll-like receptors [TLRs]) on the surface of the phagocytes that are specific for certain molecules distinctly expressed by bacteria, fungi, and viruses. Engagement of TLRs (see later) activates the phagocytes to release inflammatory mediators that affect endothelial cells in the immediate vicinity. These changes in the endothelial cell surface and the presence of numerous soluble inflammatory mediators cause circulating PMNs to withdraw from the circulation and adhere to the "inflamed" endothelium. After tightly adhering to the endothelium, the PMN begins a process of diapedesis through adjacent endothelial cells and the intact underlying basement membrane. When the PMN has penetrated the basement membrane, the cell emigrates from the blood vessel into the area of inflammation.

Initial random migration (chemokinesis) becomes highly directed (chemotaxis) by the increasing concentration of chemotactic factors secreted by activated monocytes and macrophages. Other chemotactic agents generated at the site of infection include products of complement activation and some byproducts of the microorganisms. On reaching the area of bacterial invasion, the PMN ingests encountered microbes and begins a process of biochemical activation resulting in generation of reactive oxygen intermediates and other metabolites, which are used to kill the pathogen. Selected aspects of this complex process are described further later on.

ADHESION

PMN adhesion to endothelial cells is a crucial step in the recruitment of these leukocytes to inflammatory sites. Although PMNs can adhere to normal or activated vascular endothelium, inflammation is associated with hemodynamic

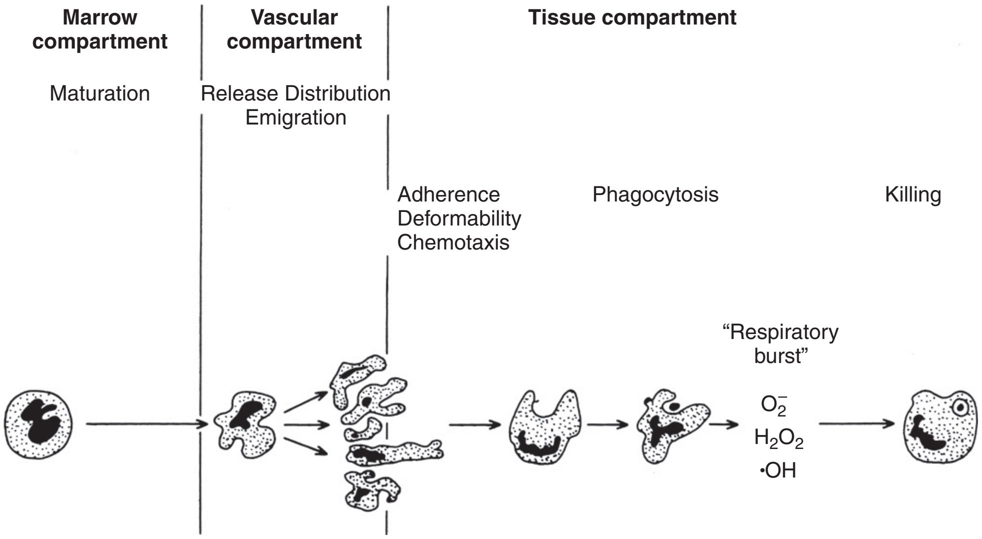

Figure 39–1. Overview of polymorphonuclear neutrophil (PMN) functions. PMNs are produced and mature in the bone marrow over a 2-week period. On release from the marrow, PMNs circulate for 6 to 8 hours before emigrating into tissues. At sites of infection, chemotactic factors enhance PMN adhesion to and emigration through vascular endothelium, and PMNs migrate in a directed fashion (chemotaxis) toward the pathogens. Phagocytosis of the offending organisms stimulates an increase in production of oxygen metabolites (respiratory burst), which facilitates PMN killing of the ingested microbes.

and biochemical changes in blood vessels that facilitate leukocyte adhesion to the vessel endothelial lining. It is now apparent that a series of changes in the expression of specific glycoproteins occurs on the leukocyte and the endothelial cell surface during inflammation.

One family of structurally and functionally related proteins found on the plasma membrane of all myeloid cells seems to mediate many adhesion-related neutrophil functions (i.e., chemotaxis, phagocytosis, degranulation, and aggregation). These cell surface glycoproteins belong to the integrin family of receptors and are designated CD11/CD18 leukocyte adhesion molecules. Each heterodimeric protein consists of one immunologically distinct α subunit (leukocyte functional antigen-1; CD11a, Mac-1; CD11b, P150, 95; CD11c), but all share a common β subunit (CD18). Monoclonal antibodies directed against CD11b/CD18 inhibit PMN aggregation, spread, chemotaxis, and adhesion to endothelial cells. CD11b/CD18 and CD11c/CD18 serve as complement receptors and mediate complement-coated (fragment iC3b) particle ingestion by PMNs. CD11a/CD18 has been shown to be important in PMN killing of target cells through antibody-dependent mechanisms. Patients with a heritable deficiency of these leukocyte cell surface glycoproteins have recurrent infections characterized by failure to accumulate granulocytes at sites of infection.

Neutrophil adhesion to vascular endothelium and to other phagocytes depends on several specific receptor-ligand interactions at the cell surface membrane (Fig. 39-2). Circulating neutrophils usually roll along vascular endothelial cells with transient interactions between neutrophil selectins on the cell surface and counter-receptors on the endothelium. When endothelial cells are activated during inflammation, more selectin counter-receptors (see Fig. 39-2) are expressed, and additional proteins (intercellular adhesion molecule [ICAM]-1 and ICAM-2 in Fig. 39-2) of the immunoglobulin supergene family, which serve as ligands for the neutrophil integrin family, are activated. The rolling neutrophil is slowed by the more concentrated interactions of the neutrophil cell surface selectins and the endothelial counter-receptors. Simultaneously, increased interactions of neutrophil cell surface integrins with endothelial ICAM-1 and ICAM-2 (see Fig. 39-2) occur, neutrophil cell surface selectins are shed, and a firm neutrophil-endothelial adhesive interaction is established. Neutrophils migrate between endothelial cells and emigrate into the tissue toward the nidus of microorganisms.

Adhesion of PMNs to artificial surfaces in vitro is comparable for unstimulated PMNs isolated from neonatal or adult blood. When PMNs from term neonates are stimulated with chemotactic factors, adhesion is greatly diminished, however, compared with cells isolated from adults. More profound deficits are displayed by PMNs from preterm infants. Less stimulated mobilization and overall expression of CD11b/CD18 glycoproteins on the plasma membrane is one important factor contributing to decreased stimulated adherence. Other causes of diminished stimulated adherence include impaired capacity to upregulate cell surface chemotactic receptors, lower granular content of lactoferrin, less fibronectin binding to the cell surface, and less shape change (failure to increase significantly overall cell surface area on chemotactic factor stimulation). Downregulation of L-selectin

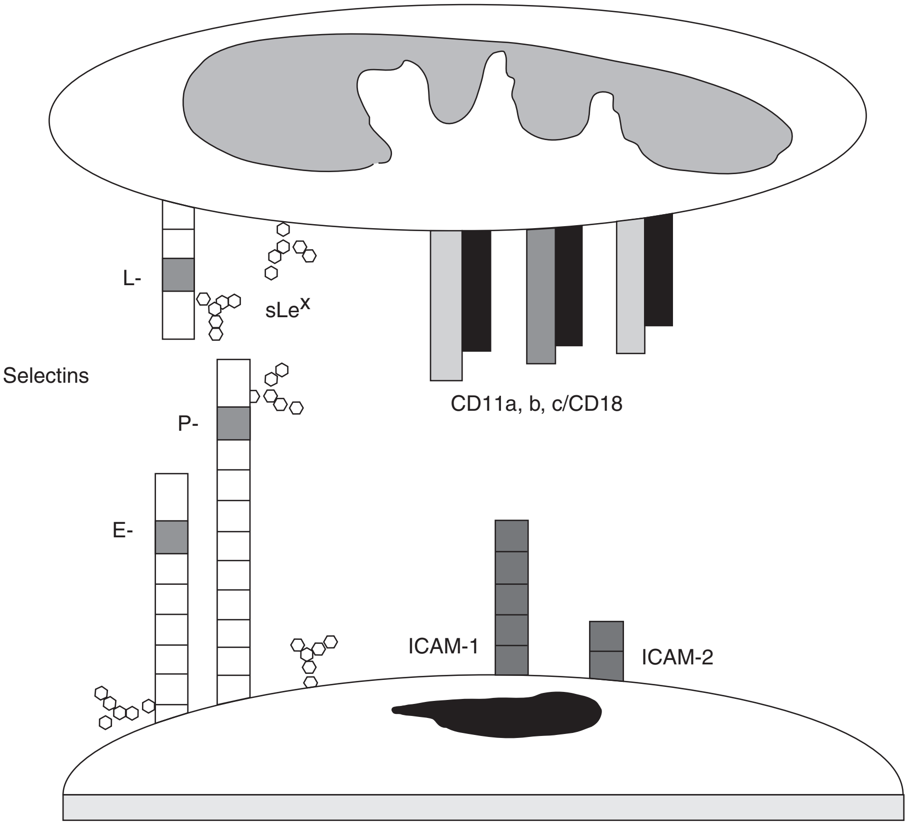

Figure 39–2. Adhesion of white blood cells to endothelial cells is mediated by several receptor-ligand pair interactions, including the selectin-carbohydrate (sialylated Lewis-x [sLe^{x}]) and integrin-immunoglobulin families. ICAM, intercellular adhesion molecule. *(From Bevilacqua MI: Endothelial-leukocyte adhesion molecules,* Annu Rev Immunol *11:767, 1993, with permission.)*

expression on term newborn cord blood granulocytes and monocytes during acute inflammation has been shown, although the pattern and level of shedding vary from neutrophils isolated from adult subjects.[24]

Normal PMNs exhibit a biphasic pattern of aggregation, followed by disaggregation when exposed to chemotactic factors. Newborn cord blood PMNs readily aggregate, but do not disaggregate when stimulated. This irreversible aggregation of PMNs would represent an impairment to cellular emigration from inflamed blood vessels if this phenomenon occurred in vivo in newborns.

CHEMOTAXIS

Chemotaxis is defined as the directed migration of PMNs toward the origin of a chemoattracting substance (see Fig. 39-1). This movement involves a series of orchestrated events, including PMN binding of the chemoattractant (by cell surface receptors), generation of an intracellular second messenger that is coupled to the receptor-ligand binding, and remodeling of the plasma membrane and cytoskeleton to produce shape changes and proper orientation of the cellular contents toward the highest concentration of the chemoattractant. Morphologically, the PMN orients toward the chemoattractant, with the leading edge (lamellipodium) of the cell becoming more spread and possessing many ruffles. Most of the intracellular organelles remain at the posterior pole of the cell (uropod). As the cell moves, the leading edge adheres to available surfaces, and contraction of cytoskeletal microfilaments (actin and myosin) pulls along the rest of the cell. Many aspects of this process are poorly developed in PMNs isolated from neonatal blood. Some of the chemotactic defects of PMNs present during the neonatal period persist throughout early childhood.

PMNs must recognize a concentration gradient of the attracting substance to move in a directed fashion. Specific cell surface receptors at the leading edge of the cell bind the chemoattractant. The number of receptors for a commonly used in vitro chemoattractant, *N*-formyl-methionyl-leucyl-phenylalanine (f-MLP), seems to be equal on PMNs from neonates and adults. When stimulated with other chemoattractants, fewer receptors for f-MLP are redistributed, however, from intracellular granules to the plasma membrane in PMNs isolated from cord blood. These cells show an apparent defect in transduction of the signals of f-MLP binding. There are significant impairments in the generation of subcellular second messengers and associated alterations in intracellular and extracellular membrane potential that are normally associated with chemoattractant binding to PMNs from adult subjects.[60] In addition, chemotactic factor stimulation fails to mobilize sufficient CD11b/CD18 to the plasma membrane, and, as discussed earlier, this complement receptor is important in many adhesion-related processes. The in vivo functional relationship of these intracellular defects to impaired chemotaxis of PMNs from neonatal cord blood remains to be clarified.

PMN movement requires dynamic cytoskeletal involvement. Despite similar baseline concentrations of filamentous (F) actin, PMNs from newborns do not generate significant additional levels of F actin after chemotactic factor stimulation compared with PMNs from adults[18]; this may impair cell movement and orientation. PMNs from neonatal cord blood fail to orient as quickly and do not sustain the bipolar configuration of chemotactic factor–stimulated PMNs isolated from adult blood.

PMNs must be deformable to emigrate from the intravascular to the extravascular space and through the extracellular matrix of tissues. PMNs from neonatal cord blood are less deformable than cells from adults. Because the energy-dependent interaction of the contractile proteins actin and myosin influences cell deformability, differences in the extent or rate of microfilament polymerization between PMNs from neonates and PMNs from adults may be relevant. Decreased deformability may also be due to the failure to generate intracellular second messengers (cyclic adenosine monophosphate) after stimulation, to overall lower intracellular concentrations of adenosine triphosphate (necessary for microfilament contraction), or to differences in plasma membrane fluidity between PMNs isolated from neonates and PMNs from adults.[36]

PMNs from term neonates are deficient in in vitro chemotactic ability. PMNs from premature infants are even more impaired. Similar deficits in PMN mobility have been shown in human newborns in vivo. When the skin of newborns is inflamed by the skin window technique, leukocyte accumulation is delayed and less intense than in adults. Overall, impaired mobility is the most consistently observed defect in PMN function in human newborns, and it contributes in a large way to the increased infectious susceptibility of neonates.

PHAGOCYTOSIS

Phagocytosis is a process of particle ingestion. Most particulate matter must be opsonized (coated) with IgG, complement fragments C3b or iC3b, fibronectin, or other proteins before being recognized and engulfed by PMNs (Fig. 39-3). After binding of the opsonized microbe by an appropriate cell surface receptor, the PMN extends pseudopods to surround the particle and form a phagocytic vacuole.

PMNs of term and preterm infants have normal phagocytic activity under most normal in vitro test conditions. These cells express diminished amounts, however, and do not upregulate the complement receptor CR3 (CD11b/CD18) when stimulated with chemotactic factors to the same degree as PMNs from adults. When stressed by a high ratio of microbes to PMNs in vitro, phagocytosis of gram-negative organisms and yeast particles by PMNs of neonates is deficient. In addition, alterations in phagocytosis have been reported for PMNs isolated from clinically stressed premature newborns. PMNs of well newborns show normal phagocytic activity, but under stressful conditions, microbe ingestion may be altered.

MICROBICIDAL ACTIVITY

Oxygen-independent and oxygen-dependent mechanisms of microbial killing are used by the PMN. Microbe disruption occurs in the phagolysosome, which is formed when the phagosome fuses with primary and secondary neutrophil granules. Within the phagolysosome, cationic proteins, lysozyme, lactoferrin, and H^+ function as oxygen-independent microbicidal mechanisms. Oxygen-dependent killing begins with PMN membrane perturbation during receptor binding of the opsonized particle and phagocytosis. A respiratory burst (an increase in oxygen consumption) ensues as reactive

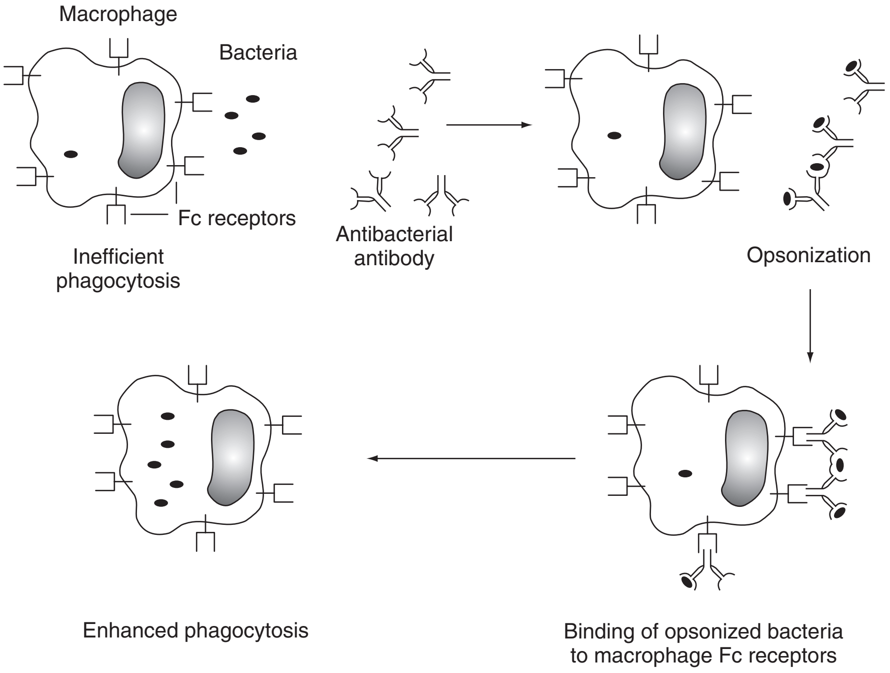

Figure 39–3. Antibody-dependent opsonization and phagocytosis of bacteria. Antibody binding to particles such as bacteria can markedly enhance the efficiency of phagocytosis. Enhancement of phagocytosis in macrophages involves increased attachment of the coated particle to the cell surface membrane and commensurate activation of the phagocyte, both of which are mediated through occupancy of Fc receptors. *(From Abbas AK et al, editors:* Cellular and molecular immunology, *2nd ed, Philadelphia, 1994, Saunders, with permission.)*

oxygen intermediates are synthesized. First, a membrane oxidase is activated that ultimately leads to production of superoxide (O_2^-), which can lead to hydrogen peroxide (H_2O_2) synthesis. These intermediate products combine to form highly reactive hydroxyl radicals. In addition, myeloperoxidase present in PMN granules catalyzes the oxidation of halides (iodide, bromide, chloride) to hypohalous acids, which are powerful oxidants that cause bacterial cell wall dissolution.

PMNs isolated from well term neonates exhibit more rapid activation of the superoxide-generating system than PMNs from adults. These cells also produce more H_2O_2 than PMNs from adults; however, there are impairments in the later phases of oxidative metabolism. Decrements in hypochlorous acid production and in quantitative measures of reactive hydroxyl radical formation have been reported. Deficiencies in certain oxygen-detoxifying enzymes such as glutathione peroxidase and catalase may cause oxidative damage to the PMNs, may serve as a source of cell dysfunction, and may decrease neutrophil viability. Overall, microbicidal activity appears normal for PMNs of term and preterm infants, unless these infants are clinically ill. When stressed, defects in killing of group B streptococci, *Escherichia coli,* and other microorganisms become readily apparent and significant.

Summary

PMNs of term and preterm infants are as capable of ingesting and killing microbial pathogens as are PMNs of adults, unless the infants are clinically ill. Under conditions of stress, these PMNs do not function with normal phagocytic and microbicidal activities. PMNs isolated from the blood of neonates consistently display diminished chemotactic and adhesion capacities. It is unclear what role these disturbed PMN functions play in causing the neonate to be so highly susceptible to systemic infections.

A rationale for the use of hematopoietic growth factors to improve neutrophil function qualitatively and quantitatively has been well established.[49] In multiple studies involving neonatal animals and human infants, administration of granulocyte CSF or GM-CSF has been documented to increase the neutrophil storage pool, induce neutrophilia, and improve many neutrophil functions. A recommendation for the use of these growth factors to decrease the incidence of morbidity and mortality associated with sepsis in newborns cannot yet be made based on published work, however.

MONONUCLEAR PHAGOCYTE SYSTEM

Production and Differentiation

The mononuclear phagocyte system comprises bone marrow monocyte precursors, circulating monocytes, and mature macrophages.[8] As with the granulocyte lineage, mononuclear phagocytes are derived from CFU-GM progenitor cells. Several hematopoietic growth factors influence mononuclear phagocyte production. CSF-1 or macrophage CSF is the major hematopoietic growth factor influencing maturation and production of mononuclear phagocytes. Cells of this lineage seem to be unique in expressing cell surface receptors for CSF-1. On leaving the bone marrow, monocytes circulate for nearly 72 hours and then migrate into tissues, where the local extracellular milieu strongly influences monocyte-to-macrophage differentiation. Although the ultimate fate of macrophages is unclear, these cells have been observed to live for several months in many human tissues.

Monocyte-to-macrophage differentiation has been well characterized, but the control mechanisms involved remain elusive. As monocytes develop into macrophages, certain morphologic changes occur. The cells increase in diameter more than threefold and acquire more cytoplasmic granules and vacuoles. Differentiation is also associated with increased expression of cell surface receptors, biosynthesis of numerous biologically active molecules, and improved phagocytic activity.[40] Similar to PMNs, all mononuclear phagocytes have a well-developed cytoskeletal apparatus that is important in determining cell mobility and participation in many adhesion-related functions.

Macrophages may be first identified in the fetus in the hematopoietic foci of the yolk sac. Before the liver becomes the major site of hematopoiesis, macrophages constitute nearly 70% of the blood cells present in the liver. Over the next few weeks, erythroblasts increase in number and predominate, with hepatic macrophages declining to 1% to 2% of all differentiated blood cells. Few macrophages are present in the developing fetal lung, but at birth a rapid influx of macrophages is observed. Macrophage populations in the lung and other organs are maintained by local proliferation of macrophages and by influx of circulating bone marrow–derived monocytes. The stimulus for monocyte recruitment into tissues at homeostasis remains unclear.

Circulating monocytes do not appear in fetal blood before the fifth month of gestation; however, at 30 weeks' gestation, monocytes increase to 3% to 7% of the circulating formed blood cells. At birth and throughout the neonatal period, circulating monocyte concentrations exceed 500/mm^3, a value considered high for adults.

Mononuclear Phagocyte Functions

ADHESION

Mononuclear phagocytes adhere to various cells and tissues, and play central roles in wound healing, inflammation, and immune responses. Similar to neutrophils, mononuclear phagocytes must emigrate from blood vessels at inflammatory sites to eradicate invading microbes. Generally, mononuclear phagocyte recruitment and accumulation lag behind the brisk PMN influx by 6 to 12 hours, but the former process persists for several days. Mononuclear phagocytes are necessary not only for host defense at inflammatory sites, but also for tissue débridement and initiation of wound repair. Inability of PMNs and mononuclear phagocytes to accumulate at sites of inflammation or injury because of impaired adhesion-related functions results in recurring, poorly healing cutaneous abscesses.

Monocyte influx into inflammatory sites is impaired in neonates compared with adults. Whether this delay results from inadequate tissue release of monocyte attractants, impaired monocyte mobility, or impaired adhesion and emigration has not been clarified. Most evidence suggests that monocyte adhesion to artificial surfaces is unimpaired during the neonatal period. Deficits in other adhesion-related functions seem to explain the delayed accumulation of monocytes in injured tissues of neonates (see later).

CHEMOTAXIS

Monocyte chemotactic activity is decreased during the neonatal period, and this impaired mobility persists throughout early childhood. Although random migration of cord blood and peripheral blood monocytes seems unimpaired at birth, decreased migration in response to chemoattractants is noted soon after. Chemotaxis of cord blood monocytes is nearly normal, but monocytes isolated from the peripheral blood of newborns do not migrate normally. The chemotactic activity of these cells sequentially declines over the first week of life before slowly improving and achieving (by age 6 years) the chemotactic activity of monocytes isolated from the blood of adults. Impaired migration in response to chemoattractants may be a primary factor in the delayed influx of monocytes at inflammatory sites during the neonatal period.

PHAGOCYTOSIS

The ability of mononuclear phagocytes to ingest a variety of soluble and particulate matter is vital to the role these cells play in the immune response. Endocytosis is important in microbial elimination, removal of senescent and transformed cells, and antigen processing for initiation of specific immune responses. Mononuclear phagocytes ingest microscopic fluid and soluble matter through a process of pinocytosis, whereas large particulate material is taken up through phagocytosis. Both processes involve cell surface membrane extension, particle enclosure, and translocation of the phagosome into the cell interior. As with neutrophils, macrophage phagocytosis is enhanced when particulate material is coated with IgG or complement fragments, and the opsonized particles engage cell surface Fc and C3b receptors.

Monocyte ingestion of *Staphylococcus aureus, E. coli, Streptococcus pyogenes, Toxoplasma gondii,* and herpes simplex virus type 2 seems quantitatively normal during the neonatal period, although the rate of ingestion may be slower. Similarly, alveolar macrophage ingestion of *Candida albicans* seems normal in newborns (who were intubated and receiving assisted ventilation) compared with the phagocytic capacity of alveolar macrophages isolated by bronchoalveolar lavage of adult volunteers.

Some evidence exists, however, of a selective impairment in phagocytosis of GBS. In these studies, monocytes isolated from neonatal cord blood ingested fewer organisms than monocytes isolated from adult peripheral blood. Phagocytosis of group B streptococci significantly increases when monocytes of newborns are incubated with organisms preopsonized with fibronectin and IgG.

MICROBICIDAL ACTIVITY

The generation of reactive oxygen intermediates is only one of several mechanisms used by mononuclear phagocytes to kill microbes. Similar to neutrophils, mononuclear phagocytes undergo a respiratory burst when particulate or soluble stimuli are engaged and ingested. The biosynthesis of O_2^-, H_2O_2, and hypohalous acids remains an important mechanism for killing of organisms by monocytes, but during the differentiation of these cells into macrophages, the magnitude of the respiratory burst diminishes, and myeloperoxidase-containing granules disappear from the cytoplasm. The reduced microbicidal function of macrophages is important because it permits these cells to remove small numbers of microorganisms from tissues without causing extensive tissue damage. Oxygen-independent microbicidal agents synthesized by macrophages include cationic proteins (defensins), lipid hydrolases, proteases, and nucleases. These agents, in combination with a highly acidified phagolysosome, seem to be cytolytically effective against many pathogenic microbes.

The microbicidal activity of mononuclear phagocytes can be regulated by cytokines. IFN-γ seems to be the most important activating agent; however, GM-CSF and TNFα also play important roles. Activated macrophages exhibit enhanced release of proinflammatory cytokines, upregulation of Fc receptors, and increased production of reactive oxygen intermediates. In contrast, IL-10 and transforming growth factor-α function as potent suppressors of some macrophage functions.

The ability of mononuclear phagocytes to generate reactive oxygen intermediates is normal during the neonatal period. Monocytes isolated from neonatal cord blood kill ingested bacteria and parasites as efficiently as cells from adult peripheral blood. Alveolar macrophages and monocyte-derived macrophages are also unimpaired in killing *S. aureus* and *C. albicans* during the neonatal period. IFN-γ production and the response of mononuclear phagocytes to exogenous IFN-γ are diminished, however, in newborns. How well fixed-tissue macrophages kill bacteria, parasites, and viruses and the response of these cells to cytokine stimulation remain untested.

Summary

The influx of mononuclear phagocytes to sites of inflammation is delayed and attenuated in newborns. This defect is most likely related to the impaired chemotactic activity displayed by the peripheral blood monocytes of these infants. Phagocytosis and microbicidal activity seem equivalent to the level displayed by mononuclear phagocytes of adults. In vivo studies of macrophage function at birth and during the neonatal period are limited, but pulmonary alveolar macrophages seem to function normally in the infants examined to date.

NATURAL KILLER CELL SYSTEM

Phenotypic and Functional Characteristics

Generally, NK cells are defined by their large granular morphology. These cells make up almost 15% of peripheral blood lymphocytes in adults and are found in several tissues, including liver, peritoneal cavity, placenta, and bone marrow. Human NK cells are defined by the expression of cell surface proteins CD56 and CD16 (low-affinity IgG receptor). NK cells lack the expression of T cell markers such as CD3. Murine NK cells are defined by the presence of the cell surface proteins NK1.1 and DX5. Similar to human NK cells, murine NK cells also lack the expression of CD3. In humans, NK cells have been subdivided further into two subsets on the basis of CD56 cell surface expression. These two NK cell subsets mediate distinct functions. $CD56^{hi}$ NK cells biosynthesize and secrete higher levels of cytokines such as TNFα, IFN-γ, GM-CSF, and IL-10 compared with $CD56^{dim}$ NK cells. $CD56^{hi}$ NK cells proliferate more efficiently in response to low doses of IL-2 compared with $CD56^{dim}$ NK cells. In contrast, $CD56^{dim}$ NK cells are more efficient at mediating NK cell cytotoxicity and antibody-dependent cell-mediated cytotoxicity compared with $CD56^{hi}$ NK cells; this is partly due to differences in the level of CD16 expression between these two subsets of NK cells.

NK cells play a crucial role in controlling viral infections and in eradicating tumor cells. NK cells recognize infected, transformed, and stressed cells in the body and eliminate them either by directly killing them or by synthesizing cytokines and chemokines, which activate several cellular components of adaptive immunity. NK cells not only play an important role in innate immunity, but also integrate various components of innate and adaptive immunity to mount an efficient immune response.

Mice that lack NK cells are susceptible to viral infections, including cytomegalovirus (CMV) infections. The gene that confers resistance to CMV infection has been mapped to an area on the chromosome that encodes several NK cell receptor genes.[62] NK cell receptors recognize virally infected cells and tumor cells and deliver a cytolytic response. Mice expressing defective NK cell cytolytic activity display impaired rejection of tumor cells in vivo. Restoration of NK cell function in NK cell–deficient mice suppresses tumor rejection and growth. Patients with mutations in the gene that encodes the transcription factor nuclear factor-κB (NF-κB) have defective NK cell activity despite normal numbers of NK cells, suggesting that NF-κB activity must regulate a crucial aspect of NK cell cytolytic function. Subsequent studies have shown that NF-κB plays an essential role in regulating the expression of perforin in NK cells. Perforin is known to play a crucial role in regulating NK cell cytolytic functions, and deficiency of perforin in NK cells impairs their cytolytic activity against virally infected host cells and tumor cells.

As discussed, NK cells recognize virally infected, stressed, and transformed cells through cell surface receptors. Generally, NK cells survey tissues and cells in the body for the expression of "self" major histocompatibility complex (MHC) class I molecules.[6,9] In the absence of adequate levels of MHC class I expression on autologous virally infected, transformed, or stressed cells, NK cells through their activating receptors deliver a "lethal hit," destroying them. In addition to expressing activating receptors, NK cells also express inhibitory receptors, however, that recognize normal levels of specific self MHC class I molecules on autologous cells and deliver an inhibitory rather than an activating signal, protecting normal cells from the cytotoxic effects of NK cells.

The mechanism by which an extracellular signal is converted into a series of intracellular events that eventually result in a cytotoxic response by NK cells is regulated partly by small signaling enzymes and adapter proteins in the cell. Activating NK cell receptors are associated with intracellular signaling molecules that contain a signature amino acid sequence known as the immunoreceptor tyrosine-based activation motif (ITAM).[6] ITAMs that activate NK cell receptors are essential for delivering the "lethal hit" to target cells, including virally infected and tumor cells. In contrast, inhibitory NK cell receptors are associated with intracellular signaling molecules that contain motifs crucial for inactivating NK cell cytotoxic functions. These motifs are known as the immunoreceptor tyrosine-based inhibitory motifs, and are closely associated with MHC class I molecules.

Together, immunoreceptor tyrosine-based inhibitory motifs and MHC class I molecules deliver a negative "off" signal to NK cells, protecting normal cells from the cytotoxic effects of NK cells. Under normal conditions, a fine balance between activating and inhibitory receptor function is maintained, which is essential for protecting normal autologous cells from the cytolytic activity of NK cells. In addition to using NK cell receptors, NK cells can mediate target cell killing by antibody-dependent cellular cytotoxicity on binding to IgG-coated cells through cell surface CD16 receptors. Collectively, these characteristics enable NK cells to act as a first line of defense, playing an important role in natural resistance against cancer and various infectious diseases.

Production and Differentiation of Natural Killer Cells

NK cells develop in human bone marrow from $CD34^+$ stem/progenitor cell precursors. The development of NK cells in the bone marrow requires the presence of the early-acting cytokines stem cell factor and Fms-like tyrosine kinase-3 (Flt3) ligand.[6] In addition to the requirement for stem cell factor and Flt3 ligand during the early phases of NK cell development, IL-15 is necessary for later stages of NK cell development and maturation. Mature NK cells express the IL-15 receptor α chain, the IL-2/15 receptor β chain, and the common cytokine receptor chain (γ-c), but do not express the IL-2 receptor α chain that is necessary for the formation of the high-affinity IL-2 receptor. Although high doses of IL-2 can stimulate NK cell proliferation, NK cell development is normal in mice that are deficient in the expression of IL-2 in vivo.

In contrast, NK cell development is impaired in vivo in mice that are deficient in the expression of either IL-2/IL-15 receptor β or γ-c genes.[6] These results suggest that IL-15 is indispensable for NK cell development, and that the α chain of the IL-15 receptor plays a unique role in the development of NK cells. Bone marrow stromal cells secrete IL-15, and exogenously added IL-15 supports NK cell development in vitro from human $CD34^+$ progenitor cells in the absence of bone marrow stromal cells. Likewise, in the murine system, IL-15 is necessary for the differentiation of functional NK cells in vitro.

Transcription Factors in the Development and Function of Natural Killer Cells

In addition to an essential role for cytokines in the development and maturation of NK cells, transcription factors play a crucial role in regulating the development of NK cells in vivo. Mice that lack the expression of the *ID2* gene show a significant reduction in NK cell numbers, although the generation of other lymphoid lineage cells is unaffected.[6] Genetic ablation of the Ets family of transcription factors also results in impaired NK cell lineage commitment. In mice, the production of IL-15 from bone marrow–derived stromal cells is partly regulated by the transcription factor, IFN regulatory factor-2. Deficiency of IFN regulatory factor-2 in mice results in impaired production of IL-15, and consequently these mice do not show terminal NK cell maturation. Genetic ablation of IFN regulatory factor-2 in mice also results in abnormal NK cell development and function. Taken together, the development of NK cells is complex and depends on several factors, including the regulation of cytokines by transcription factors.

Natural Killer Cell Function in Neonates

Most NK cells developing in human neonates express the CD16 and CD56 antigens. The percentage of NK cells in peripheral blood of newborns is similar to that of adult subjects. The absolute number of NK cells at birth is approximately twice that found in adult peripheral blood, presumably because of the higher total lymphocyte count. A small fraction of the neonatal NK cells fail to express CD56 and show poor cytolytic responses to target cells. In addition, compared with CD56-expressing NK cells, CD56-deficient NK cells do not respond well to exogenous IFN-γ stimulation. NK cell–mediated cytolysis in vitro generally is diminished during the neonatal period and early childhood. Defects in binding and lysis of target cells have been reported and are partly explained by impaired release of NK-derived IFNs and soluble cytotoxic factors. Baseline NK cell activity during the neonatal period is 30% to 80% of that of adult NK cells; however, treatment of NK cells with exogenous IL-2, IL-12, and IL-15 in vitro augments the cytolytic activity of NK cells derived from neonates. Nevertheless, the stimulated NK cell response in neonates remains suboptimal compared with adult NK cells. NK cells derived from neonates are functionally distinct from NK cells found in adults.

The functional defects in the development of NK cells in neonates have been proposed to be due partly to reduced expression of the γ-c chain on neonate-derived NK cells. The common γ-c chain is shared between cytokine receptors for IL-2, IL-4, IL-7, IL-9, and IL-15. Cord blood–derived NK cells express approximately one third of the level of γ-c chain expressed by NK cells. In vitro culture of the cord blood–derived NK cells induced a significant increase in the expression of γ-c chain, suggesting that reduced expression of γ-c chain in neonate NK cells may contribute significantly to infections in neonates.

Mutations in the γ-c chain in neonates have been linked to severe combined immunodeficiency (SCID) and profound reduction in NK cells. SCID is a rare, fatal syndrome characterized by profound deficiencies in lymphocyte function, including NK cells. Although most mutations resulting in SCID remain unknown, some studies have suggested a link between SCID and mutations in genes encoding adenosine deaminase, the γ-c chain of the IL-2 receptor and several other cytokine receptors, and Janus kinase 3, the intracellular signaling molecule that relays receptor-induced signals from the membrane to the nucleus.

Summary

NK cells are relatively normal in number in the neonatal period, but surface membrane expression of certain antigens is altered compared with adult NK cells. NK cell cytolytic activity against target cells in vitro is diminished during the neonatal period. The role of NK cell immaturity in contributing to the increased susceptibility of newborns to viral infection remains to be determined.

Humoral Components

OVERVIEW OF SERUM OPSONINS

The role of humoral factors in the enhancement of leukocyte phagocytosis of bacterial pathogens has been known since the turn of the 20th century. These heat-labile and heat-stable plasma proteins, called opsonins, consist mainly of serum antibodies and components of the complement system, although several other proteins seem to play important roles (see later). The opsonic activity of plasma or serum from newborn term infants is equivalent to activity measured in sera from adults until the test concentrations of plasma or serum are reduced to less than 10%. At low serum concentrations, opsonic activity against various bacteria and fungi is diminished during the neonatal period. Opsonic activity is reduced even more in premature infants and persists at test concentrations of plasma or serum greater than 10%. These deficiencies in opsonic activity may be related partly to lower complement and IgG and IgM concentrations in newborns. The complement system is described in the following section. The opsonic role and other functions of immunoglobulins are reviewed later, when antibodies are discussed as humoral components of specific immunity.

COMPLEMENT SYSTEM

Activation Pathways and Overview of Functional Products

The complement system plays an important role as one of the principal humoral effector pathways of immunity.[48] Its major function is to facilitate the neutralization of foreign substances either in the circulation or on mucous membranes. This function is accomplished by a series of plasma proteins that are involved in specific and nonspecific host defense mechanisms.

The classic pathway of complement activation requires the presence of specific antibodies against a particular antigen and the formation of immune complexes (Fig. 39-4). Two antibody molecules of the immune complex are bridged by the first component of complement, C1, which initiates a chain reaction in which one activated component serves as the enzyme that cleaves the next component in line. The order of component activation in the classic pathway is C1, C4, C2, and C3. Peptides with different biologic activities are created and either remain attached to the site of activation or diffuse into the milieu. The third component of complement, C3, is cleaved into membrane-bound C3b and the fluid phase C3a. With the generation of C3b, the classic pathway merges with the other mode of complement activation, the alternative pathway.

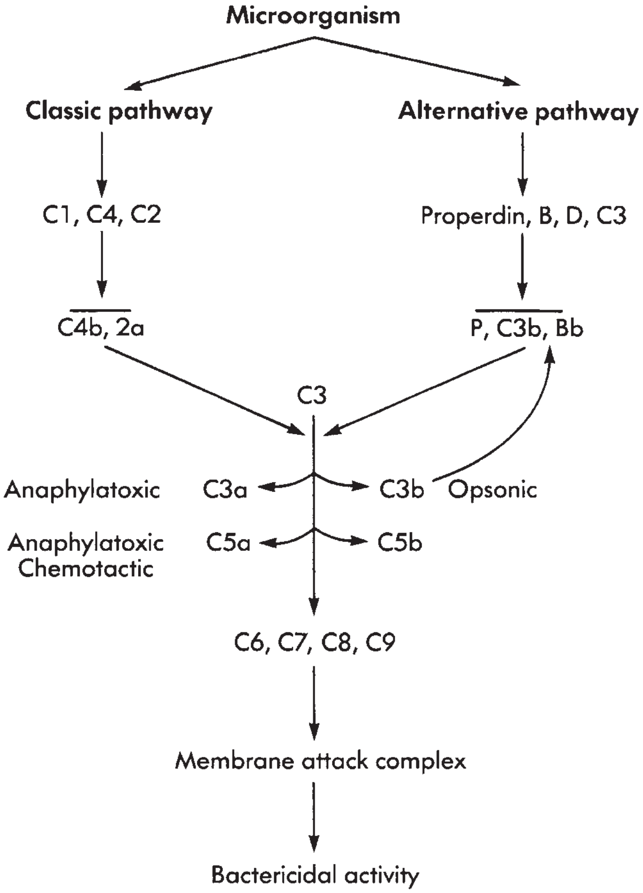

Figure 39–4. Complement system activation cascade. Activation of the classic pathway *(left)* and the alternative pathway *(right)* causes generation of soluble factors that amplify phagocyte functions and produces a membrane-bound attack complex that damages cell membranes. *(From McLean RH et al: Genetically determined variation in the complement system: relationship to disease,* J Pediatr *105:180, 1984, with permission.)*

In contrast to the classic pathway, the alternative pathway may be activated by bacterial or mammalian cell surfaces in the absence of specific antibodies. This activation is possible because small amounts of C3 in the circulation are constantly being converted to C3b. This complement component can bind to cell surfaces, interact with the next alternative pathway components in sequence (factors B and D), and form a potent enzyme for further C3 activation (C3bBb). C3b originally generated by the classic pathway may involve this amplification loop of the alternative pathway and significantly enhance local C3 activation.

The central location of C3 in the complement pathway is important not only because the classic and alternative pathways converge at this point, but also because many biologic effects are determined by the interaction of this important molecule with various regulatory systems. The direction in which the complement pathway proceeds depends on the surface to which the C3b molecule is bound. Certain bacteria and other membranes offer a “protective surface” that favors the binding of C3b to factors B and D and the assembly of the enzyme that converts the next component in line, C5, into two biologically active fragments. The smaller product, C5a, acts as an anaphylatoxin to promote many aspects of acute inflammation, including chemoattraction of leukocytes and increasing vascular permeability. The larger fragment, C5b, remains attached to the C5 convertase on the membrane and assembles the components of the membrane attack complex: C5b, C6, C7, C8, and C9. Insertion of this complex into the cell membrane results in loss of membrane functions and cellular integrity.

In the absence of a protected site, C3b is exposed to factors I and H, which facilitate cleavage of C3b into iC3b and C3d. All these fragments of C3 can function as ligands for cellular receptors, which are located on erythrocytes and almost all immunocompetent cells. The C3b receptor (CR1) is known to mediate adherence of complement-coated complexes to erythrocytes, neutrophils, and mononuclear phagocytes and plays an important role in the clearance of immune complexes, bacteria, and cellular debris from the circulation. Other receptors also have been identified, such as the C3b-binding protein, CR2, which is found on B lymphocytes and eosinophils. Its function awaits clarification, but there is evidence that adherence of the Epstein-Barr virus is mediated by this receptor. Finally, the iC3b receptor (CR3, CD11b/CD18) seems to be important for the ability of the host to overcome bacterial invasion. As previously mentioned, patients with a genetic deficiency of leukocyte cell surface CR3 experience severe recurrent bacterial infections.

Ontogeny and Analysis of the Complement System in the Neonatal Period

Complement proteins are synthesized early in gestation. Synthesis of C2, C3, C4, and C5 can be confirmed between 8 and 14 weeks of gestation. Most evidence, derived through several methods, confirms that there is no transplacental passage of complement components.

The components of the classic complement system and their functional activity (measured by total hemolytic complement assay) in full-term neonates are nearly comparable with those of normal adults (Table 39-1). In some studies in which neonates were compared with their mothers, significant deficiencies in complement component concentrations were reported (approximately 50% of adult levels). These studies did not take into account that many complement components are acute-phase proteins, and their serum concentration during pregnancy is significantly elevated compared with other normal adults. Preterm neonates have significantly decreased concentrations, however, of C1q, C4, C3, and total hemolytic complement compared with term neonates. There is a statistically significant correlation between increasing birthweight or gestational age and serum concentrations of these components.

Alternative pathway activity and individual alternative pathway components are more deficient in concentration than classic pathway activity and components in term and preterm infants (see Table 39-1). Although the concentration of alternative pathway components in some newborn term infants is equivalent to the concentration in adults, most of these infants have lower measurable alternative pathway activity. In contrast to some classic pathway components, there is no correlation between factor B concentration and gestational age. Most serum alternative complement component values are equal to values measured in human adults by the first year of life (6 to 18 months of age).

TABLE 39–1 Summary of Published Complement Levels in Neonates

	MEAN PERCENTAGE OF ADULT LEVELS	
Complement Component	**Term Neonate**	**Preterm Neonate**
CH_{50}	56-90	45-71
AP_{50}	49-65	40-51
C1q	65-90	27-58
C4	60-100	42-91
C2	76-100	96
C3	60-100	39-78
C5	75	—
C6	47	—
C7	67	—
C9	14	—
B	35-59	36-50
P	33-71	13-65
H	61	—
iC3b	55	—

Summary

Whether deficiencies in the complement system predispose a neonate to infection has not as yet been established.[48] Defects in the complement system and in the alternative pathway, in particular, are likely ultimately to be found to play a role in susceptibility to infection, especially in preterm infants. Newborns have a limited spectrum of antibody transmitted across the placenta; they receive IgG, no IgM, and little antibody to the entire range of gram-negative bacteria. The classic pathway has relatively little value at and shortly after birth. It follows that, in the absence of specific antibody, nonspecific activation of the biologically active fragments and complexes of the complement system through the alternative pathway becomes an extremely important defense mechanism for neonates during the first encounter with many bacteria. In most neonates, the functional deficiency of the alternative pathway, in conjunction with impaired functioning of PMNs, is likely to be clinically relevant.

FIBRONECTIN

Fibronectins are a class of multifunctional, high-molecular-weight glycoproteins that serve to facilitate cell-to-cell and cell-to-substratum adhesion. As adhesive ligands, fibronectins play an important role in directing cell migration, proliferation, and differentiation. Fibronectins seem essential for certain aspects of embryologic development of the fetus and for hemostasis, hematopoiesis, inflammation, and wound healing. In many pathophysiologic conditions (e.g., sepsis, thrombosis, cancer, organ fibrosis), the normal structure, physiology, and function of fibronectins are altered in a way that contributes to the underlying tissue or organ dysfunction.

Structure and Function

Fibronectins exist as soluble and insoluble dimeric molecules. Plasma fibronectin circulates at a mean concentration of 330 μg/mL in human adult peripheral blood. Soluble fibronectins have been identified in nearly every body fluid tested (synovial, ocular, pleural, amniotic, cerebrospinal, and others). Insoluble fibronectins are present in many connective tissues and extracellular matrices throughout the body. It is apparent that structural variants (isoforms) of fibronectin exist, and that expression of these isoforms is highly regulated in a cell-specific and tissue-specific fashion.

All fibronectins are capable of binding to multiple ligands simultaneously. The modular design of these glycoproteins translates into a linear array of active globular functional domains. Fibronectins display individual binding sites for some molecules and multiple sites for others. Fibronectins bind certain bacteria, heparin, fibrin, IgG, and DNA in several separate domains, but other bacteria, matrix molecules, actin, complement component C1q, and gangliosides are bound at unique sites in individual domains. In this way, fibronectin facilitates the interaction of cells with other cells, bacteria, tissues, particles, and soluble proteins.

Circulating plasma fibronectin concentrations are reduced in fetal cord blood (120 μg/mL) and in term infants (220 μg/mL). Premature infants of 30 to 31 weeks' gestation have significantly lower plasma concentrations (152 μg/mL) than term infants. Lower plasma concentrations in neonates are correlated with decreased synthetic rates, but plasma clearance of fibronectin also is measurably slower. Plasma fibronectin concentrations are reduced further in infants with respiratory distress syndrome, birth depression, sepsis, and intrauterine growth restriction.[13] Fibronectin biosynthesis by macrophages in vitro is decreased in the neonatal period.

Role in Immune Responses

Fibronectin improves leukocyte function in vitro. Plasma fibronectin and proteolytic fragments of fibronectins promote human adult peripheral blood neutrophil and monocyte chemotaxis, adhesion, and random migration. In addition, fibronectin enhances phagocyte ingestion, reactive oxygen intermediate production, and killing of opsonized (complement or IgG) yeast and bacterial organisms. Fibronectin seems to play an important role as an enhancer of phagocyte function.

Summary

Circulating concentrations of fibronectin are decreased in the neonatal period and are correlated with gestational age. Even lower plasma concentrations are measured in infants who are ill. Plasma fibronectin increases phagocyte function in vitro. The role of fibronectin in host immune defense in neonates remains uncertain, but in vitro data suggest a potential role as an enhancer of phagocyte function.

OTHER HUMORAL FACTORS

C-Reactive Protein

C-reactive protein (CRP) is an acute-phase reactant originally identified by its ability to bind to a pneumococcal polysaccharide antigen. This protein has strong functional similarity to the complement component C1q binding domain of IgG, and similar to IgG is able to activate the classic complement pathway by binding C1q. The polysaccharide antigen recognized by CRP is expressed by many bacteria and some fungi. When CRP binds to the antigen, and the complement system is activated, the organism is effectively opsonized, and rapid clearance occurs through neutrophil, monocyte, or macrophage phagocytosis.

CRP is synthesized by the fetus and the newborn. Serum concentrations seem equivalent in uninfected neonates and adults. CRP is one of the most rapidly responsive acute-phase proteins, with increases of 100-fold to 1000-fold (in adults) in the serum concentration detectable during an infection.[31] In surveys of infants with proven infections, an elevation of CRP serum concentration has been observed in 50% to 100% of patients. Normal values of CRP are less than 1.6 mg/dL on postnatal days 1 to 2 and less than 1 mg/dL thereafter. Diminished or absent increases in the CRP concentration have been observed during the first 12 to 24 hours of life in infected newborns, particularly in newborns infected with group B streptococci. CRP levels decrease rapidly in infants who clinically respond to antimicrobial therapy and return to normal in 5 to 6 days.

Lactoferrin

Lactoferrin is a positively charged iron-binding glycoprotein present in the specific granules of neutrophils. Lactoferrin is released into the phagosome after particle ingestion and is deposited on the cell surface membrane during stimulated degranulation. This glycoprotein seems to enhance neutrophil-endothelial adhesion interactions and neutrophil aggregation, reactive oxygen intermediate production, and chemotaxis. Deficient neutrophil adherence and directed migration have been reported in studies of patients with a heritable deficiency of lactoferrin-containing neutrophil-specific granules.

Neonatal cord blood neutrophils are profoundly deficient in lactoferrin. Stimulation of neutrophils with the synthetic chemoattractant f-MLP results in degranulation of lactoferrin that is quantitatively similar to the concentrations elicited from neutrophils of adults. In contrast, lactoferrin release is diminished when neutrophils are stimulated to spread and move on artificial surfaces. The role of lactoferrin deficiency in contributing to impaired neutrophil chemotaxis is uncertain.

Collectins

Collectins are soluble proteins that play a role in innate immunity.[53] These molecules include mannose-binding lectin (MBL) and surfactant proteins A (SP-A) and D (SP-D) in humans, and the bovine molecules conglutinin, CL-43, and CL-1. Collectins share several structural features, including a collagen domain, a neck region, and a globular carboxyl-terminal C-type (calcium-dependent) lectin-binding domain. Collectins specifically recognize the patterns of carbohydrates on the outer walls of microorganisms. In essence, collectins function by binding to microorganisms and enhancing uptake and clearance by phagocytes. MBL can also function to activate the classic complement pathway in much the same fashion as the complement component C1q. MBL, SP-A, and SP-D bind to one or more receptors on phagocytes and stimulate chemotaxis, the respiratory burst, and the opsonophagocytosis of a wide variety of microorganisms, including group B streptococci.

SP-A and SP-D are synthesized by type II alveolar cells and by nonciliated bronchiolar epithelial cells. As with other components of surfactant, the biosynthesis and secretion of these collectins increase dramatically during the third trimester of pregnancy. Acute injury or inflammation results in rapid increases in SP-A and SP-D biosynthesis. SP-D protein is also found in gastric mucosal cells, and SP-A is present in small intestinal cells.

MBL is synthesized in the liver and secreted into the circulation. MBL serum concentrations vary widely (1000-fold) in adult human subjects primarily related to inherited polymorphisms in the promoter region of the gene. A wide range in cord blood MBL concentrations has been reported. Neonatal serum MBL concentrations generally are lower than the levels measured in adult serum. Relative deficiency of MBL has been associated with increased susceptibility to infections in children and in some adults.

BIOLOGY AND ROLE OF CYTOKINES IN NEWBORNS

Overview

Newborn infants have an increased susceptibility to infection because of various host defense impairments that exist during the neonatal period. The generation and maintenance of acquired immune responses are controlled by a network of regulatory glycoproteins and phospholipids that mediate the interactions between cells. These cytokines and chemokines are responsible for the generation of the immune response and differentiation of a wide variety of immune and nonimmune cells. The infant's ability to generate the right balance of proinflammatory and anti-inflammatory cytokines when challenged with an infectious agent allows him or her to recover from the encounter with minimal residua. When the balance is not perfectly controlled, morbidity and mortality are increased.[23] Unregulated production of cytokines in neonates may contribute to the development of necrotizing enterocolitis, bronchopulmonary dysplasia, and hypoxic-ischemic brain injury. The number of newly discovered cytokines is increasing on a yearly basis. This section focuses on the major cytokines involved in the immune responses to infectious agents and noninfectious stimuli, their developmental patterns in fetuses and newborns, and their coordinated role in neonatal sepsis.

CYTOKINE AND CHEMOKINE BIOLOGY

Interleukin-1 Family

The IL-1 family comprises three polypeptides with similar tertiary structures (IL-1α, IL-1β, and IL-1 receptor antagonist [IL-1ra]). IL-1α and IL-1β are translated as precursor peptides. Pro-IL-1α is fully active and resides in the cytoplasm, but can be transported to the cell surface where it has a role in cell-cell communication. IL-1α appears in the circulation only during severe disease. IL-1α and IL-1β share little sequence homology, but bind to the same receptor and have the same tertiary structure. Pro-IL-1β (the main circulating member of this family) is inactive and must be cleaved by a cysteine protease (IL-1β-converting enzyme or caspase I) before it is secreted. IL-1ra is a competitive inhibitor of the other members of the family that has no agonist activity. There are two varieties of IL receptors: The type I receptor binds all members of the family; the type II receptor binds only IL-1β. Both receptors are members of the IL-1 receptor/TLR superfamily.

IL-1 is synthesized by a wide variety of immune and nonimmune cells, including monocytes, macrophages, neutrophils, endothelial cells, and epithelial cells. Synthesis of these ILs is triggered by microbial products of inflammation, and many of the features of the inflammatory response syndrome can be directly attributed to members of this family. IL-1 production by monocytes and macrophages from term and premature newborns is equivalent to that of adults. In preterm infants with sepsis, monocyte secretion may be diminished, however, during the acute phase of the disease.

Interleukin-6

IL-6 is secreted in a variety of different molecular forms as a result of post-translational modification. IL-6 synthesis is initiated by cytokines (including IL-1 and IL-6), platelet-derived growth factor, epidermal growth factor, viral and bacterial infections, double-stranded RNA, endotoxin, and cyclic adenosine monophosphate. The receptor for IL-6 consists of two subcomponents: (1) a ligand-binding molecule that is not responsible for signal transduction (IL-6R), and (2) a non–ligand-binding signal transducer (gp130). A soluble form of the IL-6 receptor (sIL6Ra) also exists. sIL6Ra can bind to IL-6 and then interact with gp130 on cells that do not express the IL-6 receptor. IL-6 injected intravenously into human patients is less toxic than IL-1β and TNFα, but does result in chills and fever. IL-6 is known to activate T and B cells, stimulate maturation of megakaryocytes, increase the production of acute-phase response proteins, and enhance NK cell activities. Monocytes from term infants produce adequate amounts of IL-6 after stimulation with lipopolysaccharide (LPS), but not IL-1. Cells derived from preterm infants exhibit decreased production no matter what the stimuli. Circulating levels of IL-6 in newborns are lower than corresponding maternal values; however, the percentage of IL-6-positive monocytes (after stimulation with LPS) is higher in preterm and term neonates.

Interleukin-10

IL-10 is a potent anti-inflammatory/immunosuppressive polypeptide synthesized by monocytes, macrophages, T cells, and B cells in response to bacteria, bacterial products, viruses, fungi, and parasites. IL-10 decreases the synthesis of a wide variety of proinflammatory cytokines, and increases the production of naturally occurring proinflammatory cytokine inhibitors (e.g., IL-1ra). The synthesis of IL-10 is enhanced by various other cytokines, including TNFα, IL-1, IL-6, and IL-12. In contrast, IL-10 enhances B cell function and promotes development of cytotoxic T cells. IL-10 receptors are members of the class II cytokine receptor family and consist of two subunits. IL-10 production in neonates is diminished.

Interleukin-12 and Interferon-γ

IL-12 is a heterodimer consisting of two subunits (p35 and p40) encoded by different genes. The p40 subunit mediates binding to the IL-12 receptor, whereas the p35 subunit is needed for signal transduction. The p40 subunit can also form homodimers with itself that bind to the IL-12 receptor with equal affinity, but without eliciting a cellular effect. The homodimers may help modulate the effects of IL-12. The synthesis of the p35 and p40 subunits is regulated independently. In response to a given stimulus, cells secrete 10 to 100 times more of the homodimer than the heterodimer. IL-12 is produced by phagocytic cells (e.g., monocytes and macrophages) in response to bacteria and bacterial products, intracellular pathogens, and viruses. The IL-12 receptor is a member of the gp130 cytokine receptor superfamily. The IL-12 receptor consists of two subunits, and both must be activated for signal transduction. The principal cellular targets of IL-12 are T cells and NK cells. IL-12 induces the production of interferon (IFN-γ), stimulates proliferation, and enhances cytotoxicity. The production of IL-12 by cord blood–derived mononuclear cells (in response to endotoxin) is diminished; however, normal IL-12 synthesis has been observed with heat-killed *S. aureus* as the stimulus.

IFN-γ is produced by NK cells, type 1 T-helper (Th) cells, and cytotoxic T cells in response to IL-12, TNFα, IL-1, IL-15, and IL-18. The receptor for IFN-γ has two subunits; one is responsible for binding, and the other is responsible for signaling. IFN-γ induces class II histocompatibility antigens and activates macrophages, and is important for host defenses against intracellular pathogens, among other functions (Box 39-1). Synthesis of IFN-γ is greatly diminished in neonates.

Tumor Necrosis Factor Family

The TNF family has two members: TNFα (cachectin) and TNFβ (lymphotoxin). TNFα exists as a transmembrane form (prohormone) and a smaller secreted form consisting of three

BOX 39–1 Functions of Interferon-γ

- Enhances macrophage microbicidal activity
- Promotes secretion of inflammatory mediators
- Enhances host cell resistance to nonviral intracellular pathogens
- Upregulates surface Fc receptors and class II major histocompatibility complex antigens on phagocytes
- Inhibits macrophage migration
- Promotes formation of giant cells
- Induces myelosuppression
- Augments functioning of mature neutrophils
- Enhances differentiation of cytolytic T cells, natural killer cells, and lymphocyte-activated killer cells
- Activates endothelial cells
- Suppresses host protein synthesis

monomers. The soluble form of TNFα is formed by the cleavage of the prohormone by a matrix metalloproteinase disintegrin. The transmembrane and the secreted forms of TNF can be biologically active. Similar to IL-1, synthesis of TNFα is triggered by microbial products of inflammation (and by IL-1 and TNFα themselves). A wide variety of cells are capable of producing TNFα; however, monocytes and macrophages represent the major sources of this circulating cytokine.

There are two varieties of TNF receptors—TNFR-1 and TNFR-2. Stimulation of TNFR-1 reproduces many TNFα functions, including cytotoxicity and upregulation of adhesion molecules. TNFR-1 contains a cytoplasmic sequence of 80 amino acids that regulates programmed cell death. TNFR-2 may facilitate binding of TNF to TNFR-1. TNFs share many of the proinflammatory effects of the ILs, but are more likely to result in leukopenia. The production of TNFα by neonatal monocytes and macrophages is less than that in adults. Endotoxin-stimulated cord blood cells from preterm infants secrete significantly less TNF than cells derived from term infants or adults. The expression of TNF receptors may also be diminished.

Platelet-Activating Factor

Platelet-activating factor (PAF) is a potent phospholipid inflammatory mediator that is rapidly degraded by acetylhydrolase. PAF is produced by many cell types; however, only macrophages and eosinophils exhibit regulated release. PAF primarily resides on the cell surface, where it acts as an intercellular messenger. Intravenous administration of PAF results in systemic hypotension, capillary leakage, pulmonary hypertension, neutropenia, thrombocytopenia, and ischemic intestinal necrosis in animals. At a cellular level, PAF is a potent activator of neutrophils. PAF production is increased by cellular exposure to lipopolysaccharide (LPS), hypoxia, hematopoietic growth factors, TNF, IL-1, thrombin, bradykinin, and leukotriene C_4. PAF stimulates the production of other mediators, including TNF, complement, oxygen radicals, prostaglandins, thromboxane, and leukotrienes. There is a strong association (but not a proven etiologic relationship) between neonatal necrotizing enterocolitis and increased concentrations of PAF.

Chemokines

Chemokines are the largest family of cytokines and are involved in the activation and recruitment of a wide variety of cell types. Chemokines are 8- to 12-kDa heparin-binding proteins ranging from 70 to 100 amino acids in length. All chemokines contain four cysteine motifs (forming double bonds) and are classified according to the arrangement of the cysteines at the amino-terminal end. Of the four subgroups (CXC, CC, C, and CX3C), the CC and CXC are the largest (Table 39-2). Chemokine receptors belong to the seven transmembrane–spanning family of G-protein–coupled

TABLE 39–2 Human CXC and CC Chemokines and Relative Receptors

Chemokines	Systematic Name	Chemokine Receptors
GRO α	CXCL1	CXCR2
GRO β	CXCL2	CXCR2
GRO γ	CXCL3	CXCR2
ENA-78	CXCL5	CXCR2
GCP-2	CXCL6	CXCR2, CXCR1
NAP-2	CXCL7	CXCR2
Interleukin-8	CXCL8	CXCR2, CXCR1
Mig	CXCL9	CXCR3
IP-10	CXCL10	CXCR3

receptors. Chemokines are constitutively produced in organs where cell attraction is required for maintenance of local homeostasis.[12] Most chemokines are inducible by inflammatory cytokines and endotoxin. In inflammatory states, chemokines are responsible for navigation and homing of effector leukocytes. In addition, chemokines induce a wide variety of leukocyte responses, including enzyme release from intracellular stores, oxygen radical formation, shape change through cytoskeletal rearrangement, generation of lipid mediators, and induction of adhesion to endothelium and extracellular matrix proteins. Chemokines are quite diverse in their target cell selectivity. CXC chemokines generally are more selective for neutrophils and T cells, whereas CC chemokines mainly attract monocytes and T lymphocytes. Considerable data suggest that chemotactic factor generation is deficient in newborn infants.

COORDINATED INFLAMMATORY RESPONSE IN NEONATAL SEPSIS

In human bacterial sepsis, cytokines are released in a sequential manner, resulting in a cytokine cascade. After a challenge with a low dose of endotoxin, TNFα peaks within 90 minutes. Other proinflammatory cytokines are released shortly afterward, and anti-inflammatory mediators follow in close sequence. The peak in IL-10 production may not occur for hours, however. In general, cytokines are not stored in intracellular compartments; they are synthesized and released in response to an inflammatory stimulus. Regulation of cytokine production occurs at the level of gene transcription. Specific transcription factors (e.g., NF-κB) bind to DNA response elements that either inhibit or promote gene transcription. Proinflammatory and anti-inflammatory cytokines or molecules are produced in response to an inflammatory stimulus. Counterinflammatory molecules include soluble cytokine receptors (resulting from proteolytic cleavage of the extracellular binding domain), anti-inflammatory cytokines (e.g., IL-10), and cytokine receptor antagonists (e.g., IL-1ra).

Antigen-presenting cells (APCs) of the innate immune system (e.g., macrophages, NK cells, neutrophils, mucosal epithelial cells, endothelial cells, and dendritic cells [DCs]) play pivotal roles in the initiation of an inflammatory response to invading pathogens. As depicted in Figure 39-5, the macrophage is activated by endotoxin (LPS) binding to the CD14 receptor (the main LPS binding receptor) by an LPS-binding protein. CD14 also exists in a soluble form that is shed from the macrophage cell surface through the action of serine proteases. Circulating LPS-CD14 complexes can attach to endothelial cells or epithelial cells. Through this mechanism, endothelial cells are activated to produce other cytokines and mediators (e.g., PAF, nitric oxide, and IL-6) that contribute to the proinflammatory response. CD14 is also required for the recognition of other bacterial products, including peptidoglycans and lipoteichoic acid from gram-positive bacteria. The formation of the CD14-LPS complex significantly reduces the concentration of LPS needed for activation.

CD14 lacks transmembrane and intracellular domains and cannot initiate a cellular response. Another pathway involving TLRs is responsible for cell activation and signal transduction.[1] CD14 seems to be able to discriminate between bacterial products and sort their signals to different TLRs. The TLRs are named from Toll, a plasma membrane receptor in *Drosophila,* which has a cytoplasmic domain homologous to the IL-1 receptor protein. Toll receptors induce signal transduction pathways that lead to the activation of the transcription factor NF-κB. In mammalian species, there are at least 10 TLRs (Table 39-3), which represent type I transmembrane proteins characterized by an extracellular domain, a transmembrane domain, and an intracellular domain. TLRs are pattern recognition receptors that recognize pathogen-associated molecular patterns. Pathogen-associated molecular patterns are shared by many pathogens, but are not

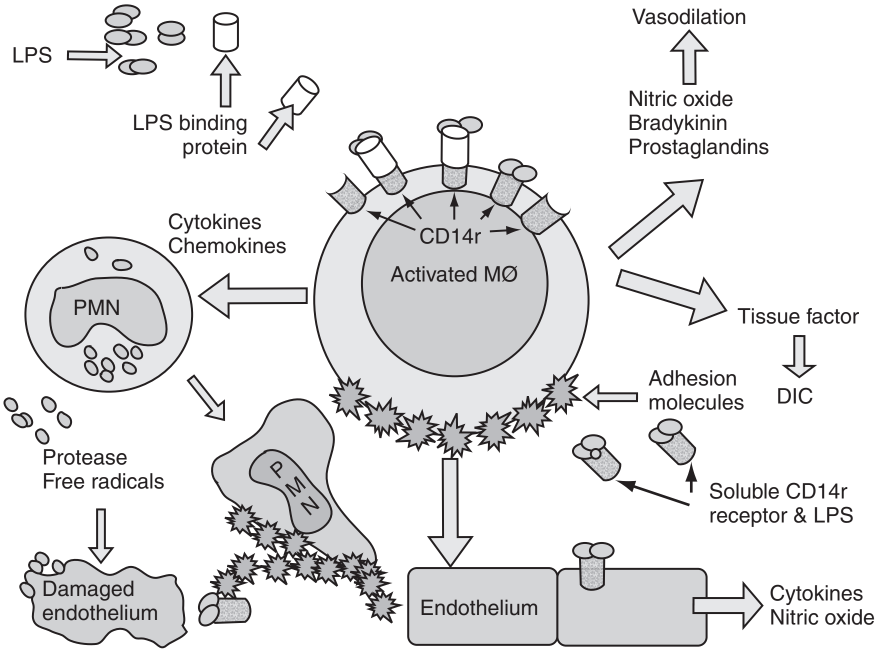

Figure 39–5. Role of macrophages in mediating the inflammatory response. Lipopolysaccharide (LPS) binding to the CD14 receptor (with or without LPS binding protein) activates the macrophage (MØ) to synthesize and secrete cytokines, chemokines, and other mediators. These soluble factors stimulate polymorphonuclear neutrophils (PMNs) to release proteases and oxygen free radicals that are important for microbial killing, but that also may injure endothelium and cause capillary leak. Binding of soluble LPS-CD14 complexes to endothelial cells promotes biosynthesis of other cytokines and small molecular mediators (e.g., nitric oxide, interleukin-6). Endothelial activation also results in upregulation of cell surface adhesive molecules that interact with neutrophil adhesive molecules and promote neutrophil extravasation. DIC, disseminated intravascular coagulation.

TABLE 39–3 Role of Toll-like Receptors (TLRs) in Pathogen Recognition and Pathophysiology of Human Disease

Toll-like Receptor	Ligands	Pathogens or Disease State
TLR1	Signals as a dimer only when combined with TLR2 for all its ligands; recognizes *Borrelia burgdorferi* OspA; required for adaptive immune response	Lyme disease
	Tri-acyl lipopeptides (bacteria, e.g., *Mycobacterium tuberculosis*)	
	Soluble factors (*Neisseria meningitidis*)	*N. meningitidis*
TLR2	Associates with CD11/CD18, CD14, MD-2, TLR1, TLR6, dectin 1; lipoprotein/lipopeptides (various microbial pathogens)	*M. tuberculosis*
	Peptidoglycan	Apoptosis of Schwann cells in leprosy
	Lipoteichoic acid	
	Lipoarabinomannan (mycobacteria)	
	Phenol-soluble modulin (*Staphylococcus epidermidis*)	
	Glycoinositolphospholipids (*Trypanosoma cruzi*)	Chagas disease
	Glycolipids (*Treponema maltophilum*)	Leptospirosis
	Porin (*Neisseria*)

expressed in host cells. TLR4 is responsible for the recognition of bacterial endotoxin. It is essential for signaling, but requires a small protein (MD-2) to confer responsiveness. Other TLRs bind cell wall products from gram-positive bacteria and fungi.

When activated, TLRs initiate a signaling cascade that shares many of the same molecules used by the IL-1 receptor. Activated, macrophages synthesize and secrete the cascade of proinflammatory cytokines, chemokines, and mediators described earlier. Some of these cytokines activate neutrophils to release proteases and free radicals that have the capacity to damage endothelium and promote capillary leak. Upregulation of adhesion molecules on the neutrophils allows them to bind to counter-receptors on the endothelial cells and migrate to sites of inflammation. The proinflammatory cascade is interrupted by the initiation of counter-regulatory mechanisms. Because most patients with life-threatening infections (i.e., systemic inflammatory response syndrome) are not admitted early in the course of their sepsis episode, proinflammatory cytokines are detected in only a subset of patients. Anti-inflammatory cytokines (which appear later in the cascade) are found in most of these infected individuals.

The concentration of anti-inflammatory substances (e.g., IL-1ra and soluble receptors) increases substantially with time and has been termed the *compensatory anti-inflammatory response syndrome*. This is a response of the host to limit the toxicity of proinflammatory substances. Shortly after the onset of an infectious episode, the mononuclear cell becomes refractory and is unable to respond to proinflammatory cytokines. In contrast, the capacity to produce anti-inflammatory substances such as IL-1ra and IL-10 is preserved. This phenomenon has been referred to as monocyte deactivation or immunoparalysis. Although the mechanism responsible for monocyte deactivation is unclear, it probably involves increased production of IL-10. The risk of infection is greatly increased during this period of hyporeactivity.

ACQUIRED IMMUNITY

Cell-Mediated and Antibody-Mediated Responses

OVERVIEW

Lymphocytes constitute almost 20% of blood leukocytes and specialize in the recognition of invading foreign antigens in the context of major histocompatibility antigens. Lymphocytes are of two major types: (1) B lymphocytes that are produced in the bone marrow, mature in secondary lymphoid organs, and subsequently differentiate into antibody secreting plasma cells, and (2) T lymphocytes that mature and differentiate into CD4+

and CD8+ subsets in the thymus and subsequently seed the peripheral blood system, including the spleen and the lymph nodes.[21,57] T cell functions include helping B cells to make antibody; killing virally infected cells; regulating the level of the immune response; and stimulating the microbial and cytotoxic activity of the immune cells, including macrophages.

Each lymphocyte expresses a cell surface receptor that recognizes a particular antigen. In the case of T cells, it is called the T cell receptor (TCR), and in the case of B cells it is called the B cell receptor (BCR). Each lymphocyte is engineered to express a receptor that is specific for only one antigen. In this way, the lymphocyte population as a whole can recognize a wide range of antigens. The antigen receptors are generated during development by a process known as somatic mutation and recombination involving a few germline genes. The antigen receptors used by B cells and T cells are different. The BCR is a surface immunoglobulin, a membrane-bound form of the antibody that eventually gets secreted. The TCR is generated from a different set of genes that encode only the cell surface receptor.

T cells and B cells recognize antigens in different forms: B cells recognize an unmodified antigen molecule, either free in solution or on the surface of other cells. T cells recognize antigen only when it is presented to them in association with molecules encoded by the MHC. The functional consequence of these differences in antigen recognition is that T cells must be presented processed antigens in the form of short peptides by accessory cells such as macrophages or DCs, whereas B cells can directly recognize antigens in tissue fluids.

The acquired immune response arises through the process of clonal recognition. An antigen selects the clones of B and T cells that express the cell surface receptors that recognize the antigen. Because the number of different lymphocyte antigen specificities is large, the number of lymphocytes available to recognize each antigen is relatively small—only a few hundred lymphocytes in an adult. In addition, because so few cells are insufficient to eradicate an invading pathogen, the first step toward the generation of a specific immune response involves a rapid expansion of antigen-specific lymphocytes. This step is followed by further differentiation of antigen-specific cells into effector cells. These events underlie the difference between primary and secondary immune responses. During the primary response, the small number of specific cells increases, and the cells undergo differentiation. If the antigen is encountered again (or persists), there is a larger population of specific cells to react with the antigen, and these cells are able to respond more quickly because they have already undergone several steps along their differentiation pathway. These lymphocytes that have been stimulated by antigen (primed) and their progeny either may differentiate fully into effector cells or may form the expanded pool of cells (memory cells) that can respond more efficiently to a future (secondary) challenge with the same antigen.

T LYMPHOCYTES

Overview

T cells develop and differentiate in the thymus before seeding the secondary lymphoid tissues. T cells recognize antigen and MHC molecules through the TCR. This receptor consists of an antigen-binding portion formed by two different polymorphic chains in association with CD3, a complex of polypeptides involved in signaling cellular activation. The antigen-binding portion may consist of an αβ chain heterodimer. In humans, the markers CD2 and CD5 are also present on all T cells (Table 39-4). Activated T cells also carry endogenously synthesized MHC class II molecules, although these are absent from resting T cells. Activated T cells may also be induced to express CD25, which forms part of the high-affinity IL-2 receptor and is important in clonal expansion.

There are two main subpopulations of T cells, which can be distinguished according to their expression of CD4+ or CD8+. These molecules act as receptors for class II (CD4+) and class I (CD8+) MHC molecules and contribute to T cell immune recognition and cellular activation. Most $CD4^+$ T cells recognize antigen associated with MHC class II molecules, and these cells act predominantly as T-helper (Th) cells. $CD8^+$ T cells recognize antigen-associated MHC class I molecules and are primarily responsible for cytotoxic destruction of virally infected cells.

Clones of mature CD4+ T cells fall into two major groups, which are functionally defined according to the cytokines they secrete: Th1 cells interact preferentially with mononuclear phagocytes, whereas Th2 cells tend to promote B cell division and differentiation. The balance of activity between these two subsets is related in part to how antigen is presented

TABLE 39–4 Cluster-Designated (CD) Molecules Found on Human T Cells

Antigen	Molecular Weight (kDa)	Comment
CD1a	49	Expressed on thymocytes
CD1b	45	Expressed on thymocytes
CD1c	43	Expressed on thymocytes
CD2	50	Sheep erythrocyte receptor
CD3	22	Part of T cell antigen receptor complex
CD4	55	MHC class II immune recognition
CD5	67	
CD6	120	
CD7	40	Possibly IgM Fc receptor
CD8	32	MHC class I immune recognition
CD25	55	Low-affinity interleukin-2 receptor
CD45	180	Expressed on memory T cells (also known as UCHLI)
CD45R	200	Expressed on virgin T cells (also known as Leu-18)

MHC, major histocompatibility complex.

to the cells, and it ultimately determines the type of immune response that develops.

The surface phenotypes of T cell populations change during T cell development. In humans, virgin T cells express the cell surface molecule CD45RA, whereas activated cells express the CD45RO isoform and higher levels of adhesion molecules, such as the β_1-integrins (CD29). The mechanism resulting in the generation of activated T cells from resting memory T cells is still unclear.

T Cell Development

Lymphocytes destined to become T cells must undergo several maturational steps in the thymus before they become mature effector T cells. In humans, the thymus develops embryologically as an outgrowth from the third and fourth pharyngeal pouches between weeks 6 and 7 of gestation. The cortex and medulla of the thymus begin to differentiate by the 10th week of gestation, and Hassall corpuscles appear the 12th week of gestation.

The undifferentiated cells that first enter the thymus (at approximately 7 weeks' gestation) do not express either the CD4+ or the CD8+ antigen, but do express the T cell markers CD7 and CD45 (CD7 may be the IgM Fc receptor, and CD45 is the common leukocyte antigen). In the thymus, T cell maturation is accompanied by the sequential appearance of surface phenotypic markers (see Table 39-4). CD1, CD2, and CD5 surface antigens appear soon after CD7 expression, whereas CD3 appears later. As gestation progresses, most cells leaving the thymus express either the CD4+ or the CD8+ surface antigen. Cells that lack both antigens (double-negative cells) retain stem cell function and possess a receptor (CD25, Tac antigen) for IL-2, which plays an essential role in T cell proliferation.

The first thymic cells to express CD4+ or CD8+ antigens express both antigens simultaneously and appear in the thymic cortex at approximately 10 weeks' gestation (Fig. 39-6). At this stage, transcribed TCR genes are first expressed on the cell surface. Production of the T cell α chain precedes production of the β chain. By the 12th week of gestation, occasional CD3$^+$ cells can be identified in human fetal peripheral blood. As gestation progresses, the percentage of CD3$^+$ cells in the peripheral blood increases, coming to represent more than 50% of T lymphocytes by 22 weeks' gestation. These CD3$^+$ cells also express either CD4+ or CD8+ antigen. By 13 weeks of gestation, CD3$^+$ T cells appear in the fetal liver and spleen, and these cells represent more than 50% of the T lymphocytes in those organs by the end of the second trimester.

Role of Cytokine Receptor Signaling in Lymphocyte Development

In humans, X-linked SCID (X-SCID) syndrome is characterized by defective T cell development and function. Affected patients lack T cells, but possess near-normal numbers of

Figure 39–6. Putative stages of human thymocyte development. Prothymocytes from the bone marrow enter the thymus and give rise to three major stages of $\alpha\beta$–T cell receptor ($\alpha\beta$-TCR) lineage thymocytes. TCR-α and TCR-β chain genes are rearranged during stage I; thymic selection occurs mainly during stage II; and emigration of mature CD4+ and CD8+ cells occurs in stage III. *(From Lewis DB et al: Developmental immunology and role of host defenses in neonatal susceptibility to infection. B cells. B cells from patients with X-SCID tend to secrete predominantly IgM antibody. Altered B cell–mediated antibody production in patients with X-SCID has been attributed to defective T cell help. The mapping of the gene that encodes the common subunit of cytokine receptors, including IL-2, has been linked to the X-SCID locus. Patients with X-SCID possess mutations in the common subunit, establishing a correlation between defects in this gene and the cause of X-SCID. Based on these observations, it was predicted that lymphocytes deficient in the expression of the IL-2 receptor would mimic some of the phenotypic abnormalities associated with patients with X-SCID. Deficiency of IL-2 or the IL-2 receptor does not result in any of the defects observed in patients with X-SCID, however. These observations have since been attributed to the presence of the common subunit of multiple cytokine receptors, including the IL-4, IL-7, IL-9, and IL-15 receptors. All these receptors are expressed on T cells, and mutations in the common subunit are likely to affect the function of all these receptors in patients with X-SCID and provide an explanation for the pathophysiologic process of this disease.

T Lymphocyte Activation and Maturation

The T cell receptor (TCR) is a multisubunit complex that consists of αβ chains noncovalently associated with the invariant CD3-γ, CD3-δ, CD3-ε, and TCR-ζ chains. T cell activation by APCs results in the activation of protein tyrosine kinases that associate with the CD3 and TCR-ζ subunits and the coreceptors CD4+ or CD8+. These activation events result in the transcriptional activation of many genes, resulting in T cell proliferation, differentiation, and acquisition of effector function.

Generally, interaction between the TCR and the antigen presenting cells (APC) results in the activation of intracellular enzymes and adapter molecules that consists of recognition sequences known as the Src homology (SH) 2 and SH3 domains containing signaling proteins that belong to the Src family of lymphocyte-specific kinase (LCK).[14] Activated LCK associates intracellularly with the TCR and with the CD8+ and CD4+ coreceptors. Activated LCK also activates the cytoplasmic domain of CD3-ζ, which contains a conserved amino acid motif, ITAM. ITAM allows the binding of additional signaling molecules such as SYK family kinase ZAP70. When recruited to ITAM, ZAP70 is activated, which subsequently activates a major adapter protein in T cell signaling termed *linker for activation of T cells* (LAT). Activation of LAT and several other signaling molecules in this cascade results in the activation of nuclear proteins, including transcription factors such as nuclear factor of activated T cells and mitogen-activated protein kinase.[14] Taken together, the successive activation of a series of intracellular signaling molecules on TCR engagement with MHC molecules on APCs results in the transcription of important T cell–specific genes that are crucial for development, differentiation, and function of T cells.

T cells require two signals for activation: a signal provided through the TCR, and a second, costimulatory signal. The CD28 molecule on T cells binds to B7-1 or B7-2 on APCs, providing the second of the two signals needed for initiation of naive T cell responses. A key feature of the costimulatory signal provided by CD28 is that, in conjunction with a TCR stimulus, it allows high-level IL-2 production and provides an essential survival signal for T cells. The combined costimulatory signal prevents T cell apoptosis or the induction of anergy (unresponsiveness) that may occur in response to activation of either signal alone.

Naive helper T cells can be divided into two subsets, based on the profile of cytokines they produce. Th1 cells produce IL-2, IFN, and TNF, and Th2 cells produce IL-4, IL-5, IL-6, IL-10, 1L-12, and IL-13. This differential pattern of cytokine expression contributes to differences in the function of these two subsets of T cells. Th1 cells are inflammatory cells responsible for mediating cell-mediated immunity. In contrast, Th2 cells act to help B cells produce antibodies. Naive T cells generally do not express mRNA for cytokines such as IFN, IL-4, TNF, or perforin. The decision of a naive T cell to mature into either Th1 or Th2 is partly regulated by the interaction between growth factors and growth factor receptors and transcription factors. For Th1 differentiation, interaction between naive Th cells and APCs results in the synthesis of IL-12. IL-12 in conjunction with transcription factors signals transducer and activator of transcription (STAT4), and T-bet drives the maturation of IFN-producing Th1 cells.[41] Likewise, IL-6, STAT6, and the transcription factor GATA-3 are essential for the generation of Th2 cells.[41] A balance between cytokines, signaling molecules, and transcription factors is essential for driving the differentiation of Th1 and Th2 cells from naive Th cells.

Role of Cytokines in T Cell Function

IL-2 was originally described as a T cell growth factor, but it is now known to have activity on various other cell types, including NK cells, B cells, macrophages, and monocytes. The synthesis and secretion of this cytokine are triggered by the activation of mature T cells. The binding of IL-2 initiates clonal expansion of activated T cells. High-affinity IL-2 receptor expression is induced on B cells by exposure to IL-4 and immunoglobulin receptor binding. The activity of IL-2 on other cell types (NK cells, macrophages, neutrophils, and lymphokine-activated killer cells) is mainly through the intermediate-affinity IL-2 receptor. A key role of the IL-2 receptor γ chain (which is also found in the receptors for IL-4, IL-7, IL-9, and IL-13) in the immune response is highlighted by the consequences of its genetic malfunction. Mutations in the IL-2 receptor γ chain are responsible for X-SCID in humans.

IL-4 is produced by a subpopulation of T cells and by mast cells. Its production follows T cell activation or cross-linkage of FcRI receptors on basophils or mast cells. IL-4 affects many cell types, promoting the growth of T cells, B cells, mast cells, myeloid cells, and erythroid cell progenitors. It promotes class switching in B cells to IgE and augments IgG1 production. Mice in which the IL-4 gene has been knocked out by targeted gene disruption are unable to make IgE. IL-4-overexpressing mice express very high IgE levels. The IL-4 effect on T cell development is to drive T cell differentiation toward a Th2 type at the expense of a Th1 response. The counterbalancing cytokine is IL-12, which cross-regulates IL-4. IL-4 has also been shown to initiate cytotoxic responses against tumor cells. The pleiotropic activity of IL-4 is reflected in the range of cell types that express IL-4 receptor. This high-affinity receptor is found on T cells, B cells, mast cells, myeloid cells, fibroblasts, muscle cells, neuroblasts, stromal cells, endothelial cells, and monocytes.

IL-7 signaling promotes cell-cycle entry and proliferation of developing T lymphocytes and B lymphocytes. In thymocytes, IL-7 signaling has been implicated in the induction and maintenance of the antiapoptotic protein Bcl-2 and has been shown to inhibit the expression of the proapoptotic factor Bax. These results suggest that one of the principal functions of IL-7 signaling in developing thymocytes is to promote cell survival.

IL-10 has important biologic effects on T cell function. Th0 and Th2 subsets of T cells synthesize IL-10, and production of IL-10 is inhibited by IFN-γ. IL-12 is made by B cells, monocytes, and macrophages, and acts synergistically with IL-2 to induce IFN production by T cells and NK cells. It is a key factor in the development of Th1 cells, stimulating their proliferation and differentiation. IL-12 enhances the cytotoxic activity of T cells. As noted earlier, IL-12 is a key cytokine for directing the T cell response to Th1.

T Cell Function in Neonates

In general, T cell responses in neonates are defective. Cord blood T cells have reduced ability to proliferate and synthesize cytokines such as IL-2, IFN-γ, IL-4, and GM-CSF. The defect in T cell functions in neonates has been attributed to qualitative and quantitative differences.[3,47] Studies showing reduced numbers of splenic T cells in neonates support the idea that lack of T cell responses in neonates is due to quantitative reduction in the overall numbers of T cells.[47] In addition to quantitative reduction, studies have also suggested that neonate T cells are primarily of the immature phenotype and lack the ability to mount a robust immune response. Additional studies have suggested a greater propensity of neonate naive Th cells to differentiate toward the Th2 phenotype rather than Th1 in the presence of endogenous neonatal APCs. The lack of Th1 differentiation from naive Th cells in neonates could result in impaired cell-mediated immunity. Taken together, studies so far point to multiple factors as contributors to neonatal tolerance (nonresponsiveness).

More recent studies have shown that neonatal T cells do not lack the ability to undergo proliferation and cytokine production when stimulated in a manner that does not require signaling through their TCR-CD3 complex. Studies comparing TCR-CD3–independent responses between adult and neonatal T cells have shown no differences in the ability of neonatal and adult T cells to synthesize IL-2 and undergo proliferation. Because efficient T cell responses in vivo require the presence of mature and functional APCs, studies using the ability of endogenous neonatal APCs to sustain proliferation in neonatal T cells showed that providing additional costimulatory signals to neonatal T cells in the context of endogenous APCs corrects the ability of these cells to induce proliferation and IL-2 production to adult levels. Neonatal T cells apparently do not possess intrinsic defects in T cell function; rather, the machinery necessary to provide costimulatory signals to neonatal T cells is defective.

Neonatal APCs such as dendritic cells (DCs) have been shown to express low levels of costimulatory molecules, including CD40, CD80, and CD86, compared with adult DCs.[10,28,44] The inability of neonatal DCs to deliver adequate levels of costimulatory signals to neonatal T cells is likely to be the cause of neonatal tolerance, in addition to lack of cytokine production, such as IL-12 by APCs and IFN-γ by naive Th cells, preventing the differentiation of these cells into Th1 cells. In addition to reduced CD40 signaling, the expression of MHC class II is also reduced on neonatal APCs, and may contribute to the reduced immune response of neonates.

As mentioned earlier, neonatal APCs show reduced expression of CD86 and CD40 costimulatory molecules. Treatment of these cells with a combination of IFN and CD40 ligand does not upregulate the expression of CD86 or CD40.[16] Neonatal APCs synthesize low levels of proinflammatory cytokines, including TNFα, IL-1β, or IL-12, in response to LPS stimulation (i.e., TLR4 ligand) and in response to other TLR ligands.[5,16,19,52] Upregulation of TLR4 and CD14 expression is not observed in neonatal APCs on LPS stimulation, and the expression of My88, a crucial adapter molecule in TLR signaling, is also reduced in neonatal APCs.[27,59] TLR4 expression is reduced on APCs derived from premature infants compared with full-term infants.[11] It is conceivable that premature infants are more susceptible to infections because of impaired TLR expression.

Examples of additional complexity in this process have also been documented. Studies have shown a differential response to TLR ligands on neonate APCs. TNFα synthesis is reduced in neonatal monocytes that are stimulated with LPS, whereas this response seems to be normal when these same cells are stimulated with R-848, a ligand for TLR7 and TLR8.[27] Neonatal APCs also show reduced IFN-γ responsiveness,[33,34] which is associated with defects in phagocytosis. The ability of neonatal monocytes to differentiate into DCs is significantly modulated, as reflected by differences in the morphologic characteristics of cord blood–derived DCs compared with adult DCs.[30] Taken together, studies so far implicate significant defects in TLR activation in neonatal monocyte/macrophage APCs.

Most studies related to neonatal DCs have been performed using in vitro generated monocyte-derived DCs (mDCs). These cells have several defects relative to adult mDCs. They tend to be immature based on low expression of MHC class II, CD80, and CD40. Even on LPS stimulation, the phenotype of these cells remains immature as reflected by continued lack of upregulation of MHC and costimulatory molecules.[26,58] The immaturity of neonatal DCs can be attributed to impaired TLR signaling, a phenomenon also observed in monocyte/macrophage–derived APCs discussed earlier. Additionally, neonatal DCs synthesize reduced levels of IL-12 in response to LPS.[15] This defect can be rescued, however, by providing exogenous IFN-γ to cultures.[15] Consistent with the above-described defects associated with neonatal DCs, these cells also show significant reduction in the priming of allogeneic cord blood–derived T cells relative to adult DCs.[15,29,30] Neonatal DCs apparently require additional mechanisms of activation to achieve the activation status of adult DCs.

When activated, they seem to be relatively competent, however.

In addition to monocyte-derived, cord blood–derived DCs, studies have suggested the presence of another group of DCs in cord blood that are characterized on the basis of lack of CD11c (a marker for myeloid DCs) expression and presence of CD123. CD123 is a marker used to identify plasmacytoid DCs (pDCs).[45] Cord blood contains a higher frequency of pDCs compared with peripheral blood. An enhanced ratio of pDC to mDC is also observed in cord blood compared with adults. Similar to mDCs, neonatal pDCs also show functional defects. They produce reduced levels of IFN-α/β.[7] Although cord blood pDCs respond to R-848 by upregulating the expression of CD40, CD80, CD86, and MHC antigens, the extent of upregulation is less in these cells compared with adult pDCs. Likewise, R-848-stimulated TNFα synthesis in cord blood pDCs is also reduced compared with adult pDCs. Neonatal mDCs and pDCs share similar functional characteristics. In adults, Flt3 ligand treatment of cells results in significant growth of cultured mDCs and pDCs derived from peripheral blood.[4] Treatment of hematopoietic progenitors from human fetal tissues and cord blood with Flt3 ligand induces differentiation of these cells into pDCs that synthesize significant amounts of IFN-α/β in response to viral stimulation.[39] Flt3 ligand could likely be used clinically to induce the expression of IFN in neonatal pDCs.

Neonatal DCs express reduced levels of MHC and costimulatory molecules such as CD80 and CD86. In addition, these cells express less IL-12 compared with adult DCs on activation of TLRs. IFN expression in cord blood pDCs is significantly reduced compared with adult pDCs. Recombinant Flt3 ligand given in vitro to cultures consisting of cord blood pDCs significantly enhances the number of pDCs, which are fully competent in secreting adult amounts of IFN subsequently.[54,56]

Compared with CD4+ neonatal Th cells, the status of CD8+ neonatal cytotoxic cells is poorly understood and remains controversial. Compared with neonatal CD4+ cells, neonatal CD8+ cells have a normal frequency of precursors; they are free of cytokine promoter modifications, such as the hypermethylation that is commonly associated with neonatal CD4+ Th cells.[55] Neonates show the presence of functional CD8+ cytotoxic T cells against congenital human CMV and Rous sarcoma virus. They also show the presence of functional memory CD8+ cells against congenital CMV.[20,32] These results suggest that under certain conditions of stimulation, despite the absence of adequate CD4+ T cell help, long-lived, functional memory CD8+ T cells can be generated by an in utero CMV infection. This type of antiviral immunity in neonates persists partly because of persistent and prolonged viral secretion associated with some viral infections, such as CMV infection. This type of infection is likely to result in sustained and continuous stimulation of CD4+ and CMV-specific, long-lived memory CD8+ T cells in utero. Whether in utero antigen stimulation could be used to develop infant vaccines for protecting neonates from viral infections is an area of active research.

In addition to defects in cell-mediated immunity, neonates manifest defects in humoral immunity. Generally, neonatal antibody responses to viral and bacterial infections are quantitatively and qualitatively different from adults. Although human neonates do mount an antibody response to pathogens, they predominantly produce IgM, and the magnitude of antibody response is significantly less than in adults.

B Cell Responses in Neonates

Several distinctions between neonatal and adult splenic B cells have been identified.[2] Neonatal B cells express reduced levels of costimulatory molecules CD40, CD80, and CD86, which results in defective T cell responses via CD40 ligand (CD40L) and IL-10. Marginal zone B cells derived from spleens of neonates tend to express reduced levels of CD21.[51] In addition, expression of a critical costimulatory receptor, TACI, is impaired in neonatal B cells, in particular in premature infants.[22]

Although these cell intrinsic factors contribute significantly to defects in antibody responses in neonates, B cell responses in neonates are also affected by external factors. Maternal derived antibodies can bind to vaccine antigens and inhibit neonatal B cells from recognizing them.[42] Additionally, serum complement levels, in particular, C3 levels, in neonates are reduced; this results in reduction in the formation of antigen-antibody complexes. The number of marginal zone macrophages in neonate spleens is also reduced compared with adults.[51] These cells play an essential role in trapping antigens. One also observes defects in the maturation of follicular DCs in neonates. Follicular DCs are crucial for attracting B cells and provide signals that result in somatic hypermutation and class switching of antibodies.

Additional defects include a lack of prolonged antibody response; this is due partly to impairment in the establishment and maintenance of antibody-secreting plasma cells in the bone marrow of neonates.[37] Although plasma cells in neonates do migrate to the bone marrow, they are impaired in their ability to thrive as long-lasting cells largely because of lack of survival and differentiation signals from bone marrow–derived stromal elements.[38] Finally, studies have also shown that in some instances administration of vaccines to neonates preferentially leads to the generation of memory B cells, rather than plasma cells. This situation has been largely attributed to reduced overall B cell receptor affinity of neonatal naive B cells for antigens resulting in an overall reduction in the strength of the intracellular signal, which may preferentially lead to the generation of memory B cells rather than plasma cells. In neonates, a significant number of B cell intrinsic factors and microenvironmental factors cooperate to regulate the development and maintenance of antibody-producing plasma cells and the preferential generation of memory B cells.[43]

Summary

Neonatal T cells are impaired in producing cytokines, notably IL-2 and Th1-type IFN-γ, under conditions of physiologic stimulation, including in response to TCR-CD3 stimulation. Neonatal T cells are not intrinsically incapable of mature function, however. Adult-level cytokine production can be elicited in human neonatal T cells by increasing the magnitude of Th1-promoting costimulatory signals. In contrast, neonatal cytotoxic T lymphocytes are capable of generating long-lasting memory effectors against several viral infections, including CMV and Rous sarcoma virus. These findings could be exploited in the future to generate vaccines for the treatment of viral infections.

Qualitative differences in neonatal T cells and APCs compared with adult cells might contribute to these deficient T cell–mediated responses of neonates. Compared with adult T cells, neonatal T cells seem to require more costimulation to achieve robust Th1 responses in vitro and in vivo. Neonatal APCs might be poorly functional in vivo and normally unable to promote vigorous Th1 responses. If APC function is augmented or supplemented, however, mature Th1 responses are promoted.

B LYMPHOCYTES AND ANTIBODY PRODUCTION

Overview of B Cell Function and Phenotypic Appearance

B lymphocytes represent 5% to 15% of circulating lymphocytes in the peripheral blood and are characterized by the presence of cell surface immunoglobulin.[21] Most B lymphocytes simultaneously express endogenously synthesized IgM and IgD and various other cell surface receptors (Table 39-5). Relatively few cells express cell surface IgG, IgA, or IgE. Cell surface immunoglobulin is similar in structure to secreted antibody and consists of four polypeptide chains (two identical heavy chains and two identical light chains) joined by disulfide bonds. Surface immunoglobulin is inserted into the lymphocyte membrane at the constant region of the immunoglobulin molecule.

TABLE 39–5 Cluster-Designated (CD) Molecules Found on Human B Cells*

Antigen	Molecular Weight (kDa)	Comment
CD5	67	B cell subset marker
CD10	100	Pre-B cell marker
CD19	95	
CD20	95	
CD21	35	Complement receptor CR2 (C3b receptor)
CD22	140	
CD23	45	IgE low-affinity receptor on activated B cells
CD25	55	Interleukin-2 receptor (low-affinity) chain
CDw32	40	Fc receptor (FcR11)
CD35	220	Complement receptor CR1 (C3d receptor)
CD45	180-220	Leukocyte common antigen
CD45R	220, 205	Restricted leukocyte common antigen

*All human B cells express surface immunoglobulin, and most B cells express class I and class II major histocompatibility antigens.

Immune responses to foreign antigens can be classified as primary or secondary (Table 39-6). The primary immune response results in an increase in the titer of antibody, which plateaus and then is catabolized. In the secondary immune response, the antibody titer is usually greater, appears more quickly, and consists almost entirely of IgG antibody (versus IgM in the primary immune response). Most important, after the primary response, the host acquires an immunologic memory of that foreign antigen by expanding the population of antigen-specific T cells and B cells. Memory B cells are prone to making IgG earlier and exhibit higher affinity antigen receptors. Although a few foreign antigens are considered T cell independent (i.e., they do not require the help of T cells), the antibody response to most antigens requires the coordinated response of T cells, B cells, and APCs (B cells, macrophages, and DCs). Two kinds of signals are required to activate B cells: The first signal is provided by the interaction of the foreign antigen with surface immunoglobulin, and the second signal originates from Th cells, which are needed for amplification of the immune response.

B Cell Development

B cell maturation occurs in two stages. In the first stage, undifferentiated stem cells mature into cells identifiable as B lymphocytes; this is an antigen-independent phase that occurs in the fetal liver and bone marrow in humans. The second stage of lymphoid differentiation is antigen dependent; during this phase, B lymphocytes are transformed into plasma cells.

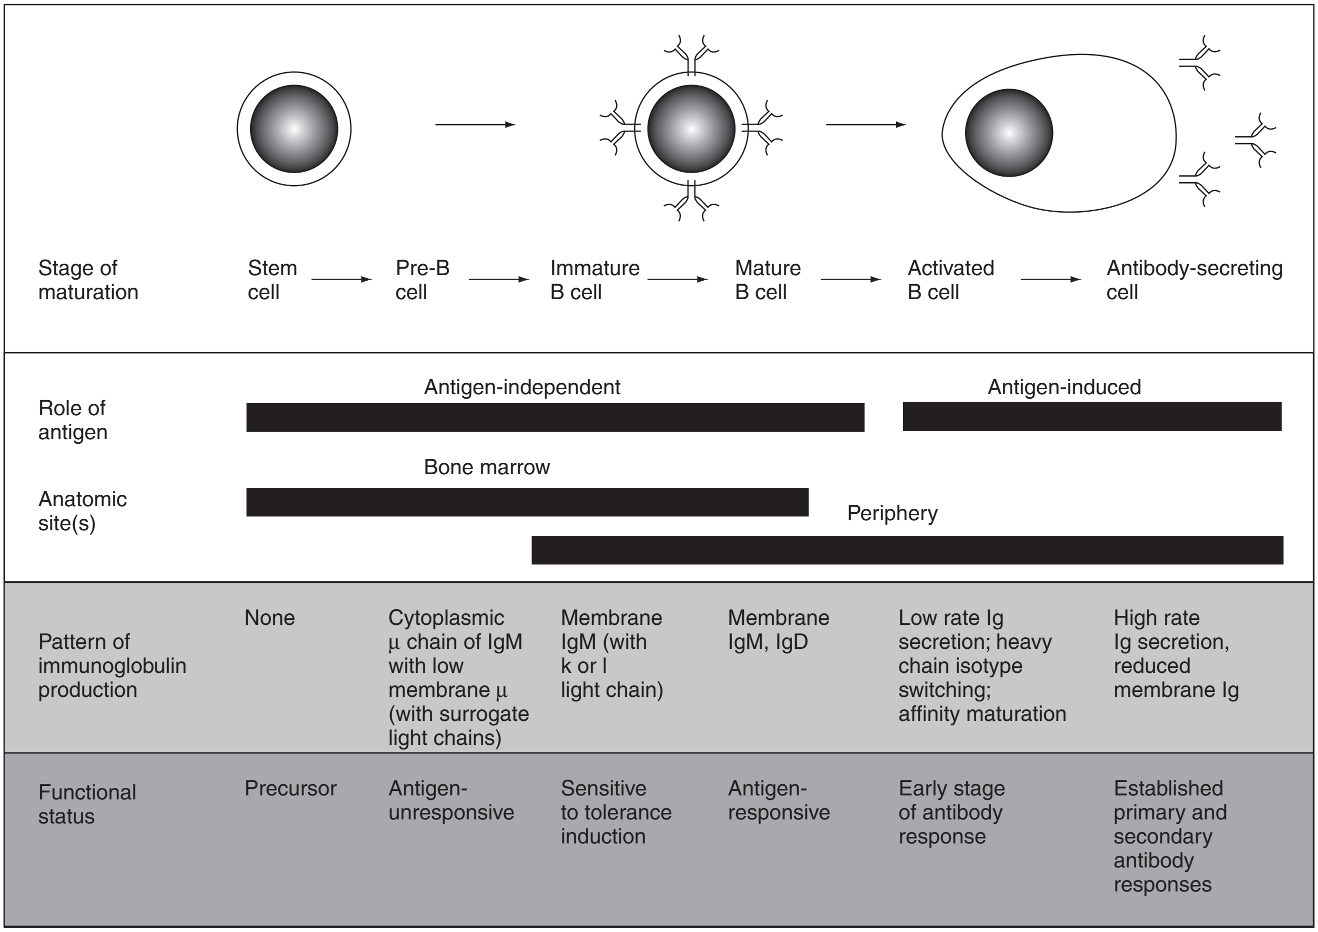
The first recognizable cell in the B cell lineage is the pre-B cell (Fig. 39-7). This cell can be detected in fetal liver by 7 to 8 weeks of gestation and is characterized by cytoplasmic staining for the heavy chain of IgM (μ chain). As gestation progresses, pre-B cells can be detected in the fetal bone marrow. Clonal diversity is generated at the pre-B cell stage of development. Intact immunoglobulin genes are formed by the rearrangement of gene segments composing each heavy-chain and light-chain family. Genes encoding the human heavy chain are located on chromosome 14; the κ light-chain genes are located on chromosome 2, and the λ light-chain genes are located on chromosome 22. The heavy-chain family consists of several hundred variable genes (*VH*), a smaller number of diversity genes (*DH*), and six joining genes (*JH*). The *JH* genes are linked to constant genes, which encode for the heavy-chain classes. The light-chain genes are similarly constructed. Antibody variable regions are generated from multiple smaller gene segments; the potential number of different antigen combining sites is the product of the number of *VH*, *DH*, and *JH* genes. Antibody diversity is additionally increased by the random addition of nucleotides at the splice site junctions of V, D, and J segments, and by point mutations in variable-region gene segments.

Pre-B cells give rise to immature B lymphocytes, which express surface IgM and complement receptors, but no other

TABLE 39–6 Features of Primary and Secondary Antibody Responses

Feature	Primary Response	Secondary Response
Lag after immunization	Usually 5-10 days	Usually 1-3 days
Peak response	Smaller	Larger
Antibody isotype	Usually IgM > IgG	Relative increase in IgG and, under certain circumstances, in IgA or IgE
Antibody affinity	Lower average affinity, more variable	Higher average affinity ("affinity maturation")
Induced by	All immunogens	Only protein antigens
Required immunization	Relatively high doses of antigens, optimally with adjuvants	Low doses of antigens, with adjuvants usually not necessary

From Abbas AK et al, editors: *Cellular and molecular immunology,* 2nd ed, Philadelphia, 1994, Saunders, p 188.



Stage of maturation	Stem cell	Pre-B cell	Immature B cell	Mature B cell	Activated B cell	Antibody-secreting cell
Pattern of immunoglobulin production	None	Cytoplasmic μ chain of IgM with low membrane μ (with surrogate light chains)	Membrane IgM (with k or l light chain)	Membrane IgM, IgD	Low rate Ig secretion; heavy chain isotype switching; affinity maturation	High rate Ig secretion, reduced membrane Ig
Functional status	Precursor	Antigen-unresponsive	Sensitive to tolerance induction	Antigen-responsive	Early stage of antibody response	Established primary and secondary antibody responses

immunoglobulin classes. These cells can be detected in the fetal liver at 8 to 9 weeks of gestation. Immature B lymphocytes have a unique functional property; when exposed to an antigen or ligand in the absence of activated T cells, they are rendered tolerant to additional stimulation with the same antigen; this process, called clonal anergy, accounts for the tolerance of B lymphocytes to self-antigens. Immunoglobulin class diversity occurs by a process of isotype switching, during which cells that express surface IgM with a particular specificity generate daughter cells that express another immunoglobulin class (Fig. 39-8). Cells that express other membrane immunoglobulin isotypes (IgG, IgA) can be shown by the 12th week of gestation. These other immunoglobulin classes almost always appear on cells that express membrane IgM concurrently.

At a later stage (the mature B cell stage), cells express membrane-bound IgG or IgA in association with membrane IgM and IgD. Cells that express surface IgD are incapable of being deactivated by antigen. In cells that express three heavy-chain classes, all three isotypes exhibit the same specificity and express the same variable-region genes. During the antigen-dependent phase of B lymphocyte differentiation, most B lymphocytes express only a single isotype, and plasma cells do not express surface immunoglobulin (see Fig. 39-7). By the 15th week of gestation, a normal fetus has levels of circulating B lymphocytes that are equal to or higher than the levels of adults. Fetal B lymphocytes can be shown in highest proportions in the spleen (30%), blood (35%), and lymph nodes (13%).

B Cell Activation by B Cell Antigen Receptors and Coreceptors

The BCR serves multiple functions on B cells that can differ substantially through various stages of their development. Proliferative expansion and differentiation are triggered through the pre-BCR and BCR complexes in pre-B cells and mature resting cells. At the opposite extreme, apoptosis is triggered in immature B cells on excessive clustering of newly expressed BCRs as a mechanism to eliminate autoreactive membrane IgM-expressing B cells. Strong BCR ligation in mature B cells has also been shown to inhibit V(D)J recombination at the membrane immunoglobulin locus, whereas weak ligation promotes recombination, presumably to generate higher affinity antibodies. Finally, the BCR serves as a specific receptor to internalize antigen efficiently for processing and peptide presentation to Th cells. The B cell has devised a complex network of BCR signaling cascades to perform such a diverse array of functions.

Role of Cytokines in B Cell Function

The cytokines IL-1, IL-2, and IL-4 affect B cell and T cell function. IL-2 stimulates the growth and differentiation of B cells. The ability of IL-4 to induce class switching in B cells has been documented earlier. This section deals in more detail with other cytokines having more specific effects on B cells.

IL-5 is produced by activated T cells. On B cells, IL-5 functions as a late-acting B cell differentiation factor, playing a major role in the production of IgA. IL-5 is perhaps better known, however, for its effect on eosinophil differentiation. It not only induces the generation of eosinophils from human bone marrow precursors, but also upregulates expression of CD11b on human eosinophils and activates IgA-induced eosinophil degranulation. T cell production of this cytokine is stimulated by parasitic infections.

IL-6 is a pleiotropic cytokine produced by many cell types, including T cells. Its effect on B cells is to promote growth and facilitate maturation of the B cells, causing immunoglobulin secretion. Resting B cells do not express the IL-6 receptor, but are induced to express the IL-6 receptor after activation.

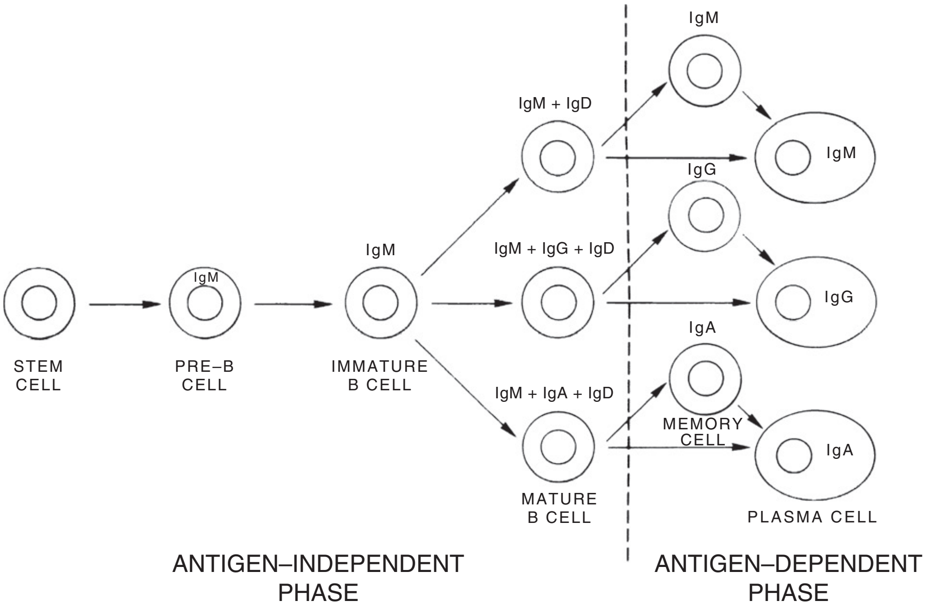

Figure 39–8. Development of B cell surface immunoglobulin expression. Immunoglobulin class diversity occurs by a process of isotype switching. Immature B lymphocytes express surface IgM, but as cells mature, surface IgM and IgD in association with IgA or IgG are expressed. During the antigen-dependent phase of B cell maturation, B cells express a single immunoglobulin isotype, and mature plasma cells are devoid of surface immunoglobulin.

IL-7 has been described previously in the T cell section, but this cytokine, which is secreted by stromal cells, has a great effect on the development of progenitor B cells. IL-10 also affects T cells and B cells, acting synergistically with other cytokines on the growth of hematopoietic lineages, including those giving rise to B cells. Antibody depletion of IL-10 in vivo results in a reduced IgM and IgA response with an increase in IgG2 and a depletion of certain B cell subsets.

IL-13 is predominantly expressed in activated Th2 cells and regulates human B cell and monocyte activity. It acts as a costimulant with CD40 receptor engagement of human B cells. Interaction between CD40 and CD40 ligand in the presence of IL-13 induces isotype switching and IgE synthesis, as does IL-4.

IL-14 is believed to play a role in the development of B cell memory. IL-14 enhances the proliferation of activated B cells and inhibits the synthesis of immunoglobulin. It is produced by follicular DCs and activated T cells. IL-14 expression in reactive lymph nodes suggests that, during a secondary immune response, surface IgD B cells migrating through the lymph node encounter antigen, become activated, and express IL-14 receptor; after binding of IL-14, the increased Bcl-2 expression prevents apoptosis and permits B cell memory development.

Immunoglobulin Structure and Function

Specific antibody may be produced in response to direct microbial exposure or through immunization by an almost infinite spectrum of antigens (e.g., proteins, carbohydrates, bacteria, viruses, fungi, and drugs). Antibodies are synthesized and secreted by B lymphocyte–derived plasma cells that reside in the lymph nodes, spleen, mucosal linings of the gastrointestinal and respiratory tracts, and bone marrow.

Antibodies comprise a unique family of glycoproteins called immunoglobulin, which in humans consists of five major classes: IgG, IgA, IgM, IgD, and IgE. The basic structure of the IgG molecule is depicted in Figure 39-9. The IgG molecule is composed of four polypeptide chains—two heavy chains and two light chains—held together by covalent disulfide bonds and noncovalent forces. In a given IgG molecule, the two heavy chains and two light chains have identical amino acid sequences. The different immunoglobulin classes are distinguished by antigenic and amino acid sequence differences in their heavy chains. Some of the immunoglobulin classes are composed of subclasses; IgG has four subclasses—IgG1, IgG2, IgG3, and IgG4—that arise from antigenic differences in the heavy chains. In addition to these differences between the immunoglobulin classes and subclasses, there

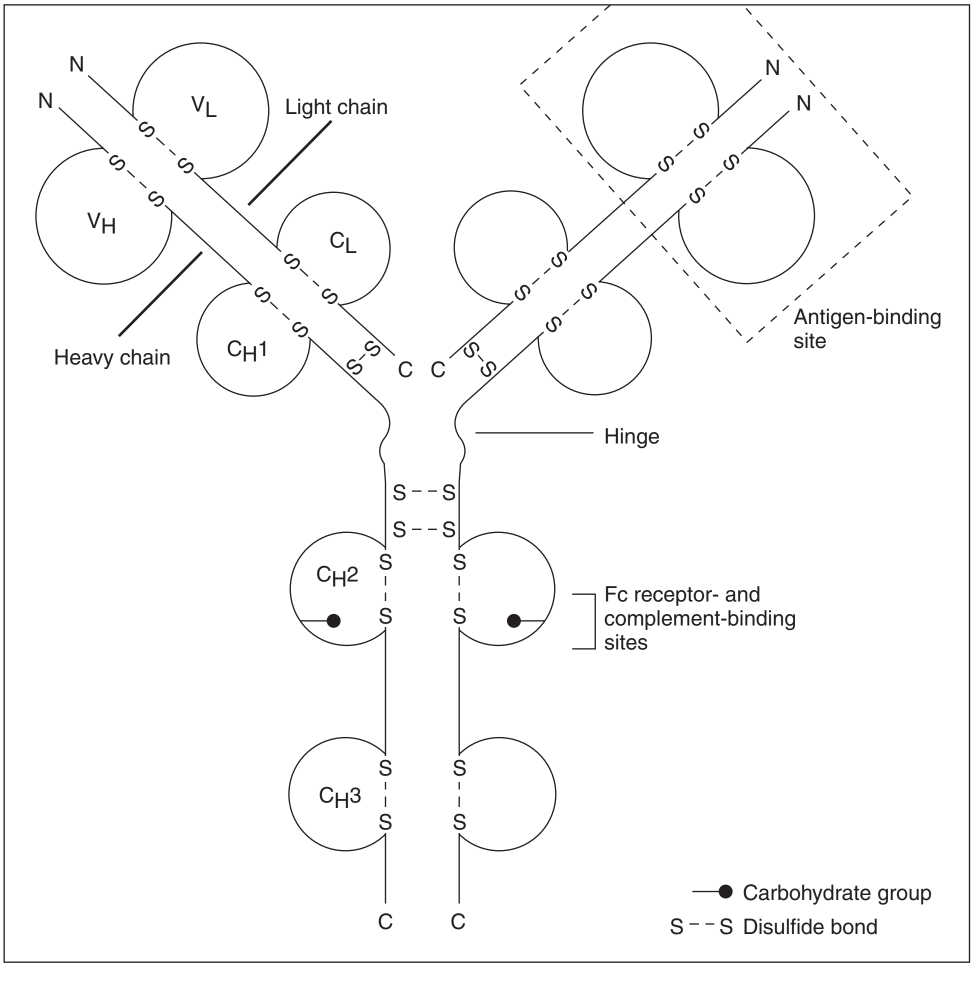

Figure 39–9. Schematic diagram of an immunoglobulin molecule. In this drawing of an IgG molecule, the antigen-binding sites are formed by the juxtaposition of light-chain (V_L) and heavy-chain (V_H) variable domains. The locations of complement-binding and Fc receptor-binding sites within the heavy-chain constant (C_H) regions are approximations. *S-S* refers to intrachain and interchain disulfide bonds; *N* and *C* refer to amino and carboxyl termini of the polypeptide chains. *(From Abbas AK et al, editors:* Cellular and molecular immunology, *2nd ed. Philadelphia, 1994, Saunders, with permission.)*

are antigenic and amino acid sequence variations in the amino-terminal portions of the heavy chains and light chains in the so-called variable (Fab) regions. The structural variability in this region permits different antibody molecules to react specifically with different antigens. In contrast, the amino acid sequences of the carboxyl-terminal portions of the heavy (Fc region) and light chains do not vary between molecules of the same immunoglobulin class or subclass; these are called the constant regions. The variable regions of immunoglobulin molecules confer the antigen-binding specificity, and the constant regions differ among the various immunoglobulin classes; these regions' biologic properties and functions vary as well. Only IgM and IgG activate the complement system through the classic pathway, and only IgG can be actively transported across the placenta.

The chemical characteristics and biologic properties of the immunoglobulin classes are summarized in Table 39-7. IgG is the major immunoglobulin in the serum and interstitial fluid and has a long half-life of approximately 21 days. It is responsible for immunity to bacteria (particularly gram-positive bacteria), bacterial toxins, and viral agents. IgG antibodies can neutralize viruses and toxins, and facilitate the phagocytosis and destruction of bacteria and other particles to which they are bound. IgG can also activate the complement pathway and amplify the inflammatory response by increasing leukocyte chemotaxis and complement-mediated opsonization.

IgA is the second most abundant immunoglobulin in serum, but it is the predominant one in the gastrointestinal and respiratory tracts and in human colostrum and breast milk. In secretions, IgA occurs as a dimer joined by a J chain and bears an additional polypeptide chain, called the secretory component. This moiety endows the molecule with resistance against degradation by proteolytic enzymes. Secretory IgA is uniquely suited for functioning in the secretions of the respiratory and gastrointestinal tracts. IgA provides local mucosal immunity against viruses and limits bacterial overgrowth on mucosal surfaces. It also may limit absorption of antigenic dietary proteins. IgA does not activate the classic complement pathway, but can activate the alternative pathway.

IgM antibodies exist in serum primarily as pentamers joined together by a J chain. IgM provides protection against blood-borne infection. It occurs only in small quantities in interstitial fluids and secretions. IgM antibodies are potent bacterial agglutinins and activate the classic complement pathway. Through activation of the complement system, IgM antibodies cause deposition of C3b on bacterial cell surfaces and facilitate phagocytosis. There are no phagocytosis-promoting receptors for IgM. Most serum antibodies to gram-negative bacteria are of the IgM type. Intrauterine and neonatal infections elicit the formation of predominantly IgM antibodies. Because IgM does not cross the placenta, the presence of specific IgM antibody in cord blood to spirochetes, rubella, CMV, or other microorganisms can be taken as reliable evidence of intrauterine infection with these agents. The absence of IgM does not exclude the possibility of congenital intrauterine infection, however.

IgE antibodies are present in extremely small quantities in serum and secretions. These antibodies play a major role in allergic reactions of the immediate hypersensitivity type. IgE antibodies bind to the cell membranes of basophils (mast cells) by a receptor for the carboxyl-terminal portion of the heavy chain. Binding of antigen (allergen) to the IgE fixed to the basophil results in the liberation of histamine, leukotrienes, and other pharmacologic mediators of immediate allergic reactions. IgD, which occurs in low concentration in serum, is present on the surface of B lymphocytes. The role of circulating IgD is unclear.

Antibody Production in Fetuses and Neonates

The fetus acquires the ability to produce serum immunoglobulins early in gestation. In vitro studies have shown the ability of fetal cells to produce antibody (IgM) by 8 weeks' gestation. IgG synthesis occur slightly later, and IgA synthesis begins at approximately 30 weeks' gestation. For numerous reasons (i.e., the sterile environment in utero, the inability of the fetus to respond to certain kinds

of antibody, T cell suppression of B cell differentiation), the fetus makes little antibody before the time of birth. As discussed later, at the time of birth, most of the circulating antibodies are IgG antibodies that have been transported across the placenta from the maternal circulation. Low levels of "fetal" IgM (<10% of adult levels) are present at term gestation and reach adult levels by 1 to 2 years of age. The concentration of IgG decreases postnatally (because of the catabolism of maternal IgG) and reaches a nadir (physiologic hypogammaglobulinemia) at approximately 3 to 4 months of age. Adult concentrations of IgG are reached by 4 to 6 years of age, and adult levels of IgA are attained near puberty (Table 39-8).

Summary

The ability to mount cell-mediated or antibody-mediated immune responses to specific antigens is acquired sequentially during the course of embryonic development. Early in gestation, fetuses can respond to certain antigens, whereas other antigens elicit antibody production or cell-mediated immune reactions only after birth. The well-known inability of children younger than 18 months of age to induce antibodies to polysaccharides from *Pneumococcus* and *Haemophilus* organisms is a clinically important example of the sequential acquisition of antigen-specific immunocompetence in humans.

Antibody responses of fetuses and premature and full-term newborns differ from responses of children and adults. Fetuses and newborns do not respond to some antigens (e.g., pneumococcal polysaccharide), and the antibody responses to other antigens (e.g., rubella, CMV, *Toxoplasma*) are predominantly of the IgM type. T lymphocytes are less experienced in neonates and may tend to suppress rather than stimulate B cell differentiation. In addition, B cells of newborns differentiate predominantly into IgM-secreting plasma cells, whereas activated adult B cells produce IgG-secreting and IgA-secreting plasma cells as well. The adult pattern of B cell differentiation develops during the first year of life.

TABLE 39–8 Normal Values for Immunoglobulins at Various Ages

Age	IgG (mg/dL)	IgA (mg/dL)	IgM (mg/dL)
Newborn	600-1670	0-5	5-15
1-3 mo	218-610	20-53	11-51
4-6 mo	228-636	27-72	25-60

PASSIVE IMMUNITY

Passive immunity is the acquisition of specific antibody or sensitized lymphocytes from another individual, and it represents a means by which specific immunity can be acquired without previous exposure to antigen or the mounting of a specific immune response. Such immunity is transient, but nonetheless may provide sufficient antimicrobial protection during a vulnerable period of life. The development of an antibody response to an antigen seen for the first time requires 7 to 14 days. Active antibody-mediated immunity is of little value during the crucial first few days of an infection with a new microorganism. The presence of circulating specific antibody to that organism (i.e., passive immunity) permits the mobilization of multiple host defense mechanisms (e.g., complement system, neutrophils) to eliminate the invading microorganism and limit its colonization. In humans, the major avenues for the acquisition of passive immunity are the transfer of IgG across the placenta and the transfer of secretory IgA through colostrum and breast milk.

Placental Transport of Antibodies

Although B lymphocytes are present in a fetus by the end of the first trimester, there is little active fetal immunoglobulin production because this process depends on exposure to antigens. Serum immunoglobulin levels in fetuses are extremely low until 20 to 22 weeks of gestation, at which time an accelerated active transport of IgG across the placenta begins. Only maternal IgG is transported. The specificity of this transport process is due to the presence of specific placental receptors for the heavy chain (Fc region) of the IgG molecule. The transport of IgG is an active placental process, and the neonate's serum IgG concentration at birth is 5% to 10% higher than that of the mother. Prematurely delivered infants have lower IgG levels than infants delivered at term; infants who are very premature (24 to 26 weeks) may have acquired little maternal antibody before delivery. Infants who are small for gestational age have lower IgG levels than infants who are an appropriate size at any gestational age. The placental dysfunction that reduces the nutrient supply to these poorly growing infants may also limit transfer of IgG. This phenomenon is manifested further by the progressive decrease in IgG transport after 44 weeks of gestation, a period when the placenta is known to become increasingly dysfunctional.

Elevated levels of IgM or IgA in cord blood usually indicate that the infant has been exposed to antigen in utero and has synthesized antibody itself. Congenital infections with syphilis and rubella characteristically produce elevation of the cord blood IgM concentration, and specific fetal antibody of the IgM type directed against the infecting agent can be detected. Elevated levels of IgM and IgA also may be found if maternal-to-fetal transplacental bleeding has occurred.

Immunologic Properties of Human Breast Milk

Maternal transfer of immunity to the newborn infant is also possible through breast milk.[17] Table 39-9 lists specific and nonspecific protective factors that are transferred to the

TABLE 39–9 Immunologically and Pharmacologically Active Components and Hormones Found in Human Colostrum and Milk

Soluble	Cellular	Hormones and Hormone-like Substances
Immunologically specific	Immunologically specific	Epidermal growth factor
Immunoglobulin: secretory IgA (11S), 7S IgA, IgG, IgM	T lymphocytes	Prostaglandins
IgE, IgD, secretory component	B lymphocytes	Relaxin
T cell products	Accessory cells	Neurotensin
Histocompatibility antigens	Neutrophils	Somatostatin
Nonspecific factors	Macrophages	Bombesin
Complement	Epithelial cells	Gonadotropins
Chemotactic factors		Ovarian steroids
Properdin		Thyroid-releasing hormone
Interferon		Thyroid-stimulating hormone
α-fetoprotein		Thyroxine and triiodothyronine
Bifidus factor		Adrenocorticotropic hormone

neonate by breast milk. Although all immunoglobulin classes can be detected in colostrum, secretory IgA constitutes most of the immunoglobulin in human breast milk. Secretory IgA consists of two "serum" IgA subunits, a J chain and a secretory component, which render it resistant to digestion by trypsin and pepsin and to hydrolysis by gastric acid. There is no evidence that immunoglobulins present in breast milk enter the systemic circulation of the human neonate.

The levels of IgA, IgM, and IgG have been studied serially in milk. The IgG concentration is relatively constant during the first 180 days of lactation, whereas IgM and IgA are highest in colostrum, decrease during the first 5 days of lactation, and remain relatively constant during the next 175 days. Breast milk contains antibodies to a broad spectrum of enteric bacteria and viruses (e.g., poliovirus, echovirus, coxsackievirus), and the antibody titers to these agents decrease in parallel to the decrease in concentrations of IgA in the milk.

Most immunoglobulins present in human breast milk are believed to be produced by plasma cells located in the breast itself, and very little milk immunoglobulin is derived from maternal serum immunoglobulins. Milk antibodies are directed predominantly against enteric bacterial and viral antigens; the concentration of such antibodies is much higher in colostrum than in maternal serum. The antibody composition of breast milk compensates partly for the deficiency of antibodies directed against enteric antigens in placentally transferred IgG. This unique spectrum of antibody specificity is achieved by the "homing" of B lymphocytes, sensitized in the mother's gastrointestinal tract, to her mammary glands. B cells stimulated by enteric bacterial or viral antigens in the Peyer patches of the small intestine migrate to the mucosal linings of the lactating mammary gland, where they differentiate into plasma cells and secrete their antibodies. Antigens introduced into the gastrointestinal tract stimulate the development of antibodies in breast milk; however, antibodies to these antigens do not develop in the serum. A mother transfers to her infant through breast milk antibodies specific for microbial agents present in her own gastrointestinal tract. As the neonate is being freshly colonized by primarily maternal flora, these antibodies limit bacterial growth in the gastrointestinal tract and protect against overgrowth.

The cellular components of human breast milk consist of macrophages, T and B lymphocytes, neutrophils, and epithelial cells. The cellular content of colostrum or early milk is higher than that of later milk and varies greatly among women. Neutrophils are present in significant numbers early in lactation, and their presence may be related to breast engorgement during the initial days of lactation. Although the function of the breast milk neutrophil is unclear, its presence does not imply infection. Epithelial cells occasionally present in milk may originate from the skin of the nipple.

Breast milk macrophages are mononuclear phagocytic cells that constitute approximately 80% of the leukocytes in milk. This is an active phagocytic cell that contains large amounts of intracytoplasmic lipid and IgA; bears cell surface receptors for IgG and C3b; and synthesizes several important host resistance factors, including lysozyme, C3 and C4 complement components, and lactoferrin. Milk macrophages are capable of phagocytizing and killing gram-positive and gram-negative bacteria and apparently interact with the lymphocytes present in breast milk.

The host defense factors that the breast milk macrophage synthesizes provide important nonspecific antimicrobial protection for neonates. Lysozyme is capable of lysing the cell walls of many bacteria. This enzyme is synthesized by the milk macrophage, and its concentration in human milk is 300 times that found in cow's milk. It is stable in an acid environment comparable with that of the gastric contents. Lactoferrin is synthesized by the milk macrophage, and its concentration in breast milk is higher than in any other body fluid. Lactoferrin antimicrobial activity derives from its ability to chelate iron, depriving bacteria of a cofactor important for their growth. The growth of *Staphylococcus* organisms and *E. coli* is limited by lactoferrin.

The C3 and C4 complement components are also actively synthesized by breast macrophages. The function of these proteins in milk is unclear because there is little IgG and IgM or the early complement components, C1 and C2, which are necessary for activation of C3 to its biologically active forms. IgA may activate C3 through the alternative pathway; however, it is found in highest concentrations in the breast macrophage itself. This macrophage-associated IgA is not synthesized, but rather is ingested by the macrophage. Viable in situ macrophages have been shown to release this IgA slowly, and this has led to the hypothesis that the breast milk macrophage may represent a vehicle for immunoglobulin transport down the neonate's gastrointestinal tract.

Viable T and B lymphocytes are present in human breast milk. T lymphocytes represent 50% of the milk lymphocytes early in lactation, declining to less than 20% as lactation progresses. The spectrum of responses of breast milk T cells differs from that of peripheral blood T cells from the same donor. Milk T cells are often unresponsive to *C. albicans* antigen, whereas peripheral blood T cells from the same donor are highly reactive. In contrast, milk T cells respond well to the K1 capsular antigen of *E. coli,* whereas peripheral blood lymphocytes exhibit minimal or no response to K1. This phenomenon may be related to the previously described homing of lymphocytes sensitized in the gastrointestinal tract to mammary glands.

The transfer of cell-mediated immunity from tuberculin-sensitive mothers to their breast-fed infants has been reported. If these reports are substantiated, this form of passive transfer of cellular immunity could be of major clinical significance. It is unlikely that intact T lymphocytes are passing from the mother's milk across the mucous membranes of the infant's gastrointestinal tract. A soluble T cell growth factor or lymphokine more likely is involved. The B lymphocytes present in milk have IgG, IgA, IgM, and IgD on their surfaces. These cells synthesize IgA almost exclusively, however. The contribution of B cells as passive immune effectors in breast milk is as yet unclear.

Summary

Maternal transfer of IgG antibodies across the placenta provides a newborn with a measure of immune protection. Antibodies to viral agents, diphtheria, and tetanus antitoxins, which are usually of the IgG class, are efficiently transported across the placenta and attain protective levels in the fetus. In contrast, antibodies to agents that evoke primarily IgA or IgM antibody responses are transported poorly or not at all, leaving the neonate unprotected against those organisms. An infant cannot be protected against agents to which the mother has not made significant amounts of antibody. Breast milk constituents may interact with the neonate's immune system in ways other than those already mentioned. A significant increase in the secretory IgA content of nasal and salivary secretions has been observed in breast-fed versus formula-fed newborns during the first few days of life. It is postulated that this increase may reflect the influence of a soluble factor in milk that acts to stimulate the mucosal immune system of breast-fed infants. Factors that enhance IgA synthesis by B cells and promote epithelial cell growth are also secreted by milk macrophages.

EVALUATION OF HOST DEFENSES IN NEONATES

Some disorders of immunologic function may become clinically apparent in the neonatal period or first year of life.[46] Because of differences in the developmental status of the newborn's host defense mechanisms and the lack of vast exposure to antigens, evaluation of the function of host defense mechanisms in the infant is different from the evaluation performed for older children and adults. Infants who have experienced two or more significant bacterial or fungal infections should be suspected of having a defect in host defense mechanisms. Patients with unusual infections (e.g., from *Pneumocystis jiroveci* [formerly *Pneumocystis carinii*]) or infections that respond incompletely to therapy and recur are also suspect. Growth failure, chronic diarrhea, chronic dermatitis, hepatosplenomegaly, and recurrent abscesses commonly occur in infants with immunologic deficiency. Primary immunodeficiency disorders are relatively uncommon, however, and numerous other predisposing conditions should be considered that may be predisposing an infant to multiple infectious episodes.

In evaluating a patient for a possible host defense mechanism defect, natural (cellular and humoral components) and acquired (cellular and humoral components) immune mechanisms should be considered and investigated. The evaluation should be divided into initial screening tests and definitive tests that allow one to establish a specific diagnosis (Box 39-2). Screening tests should be obtainable by physicians at all hospitals, but definitive tests may be available only at major medical centers.

BOX 39–2 Tests to Evaluate Neonatal Host Defense Mechanisms

NATURAL IMMUNITY

Cellular Components

- White blood cell count and differential*
- Nitroblue tetrazolium (NBT) dye reduction test*
- Random mobility and chemotaxis assay
- Phagocytosis assay
- Quantitative bactericidal assay
- Flow cytometric analysis of cell surface receptor expression
- Analysis of oxidative metabolism and enzyme activity

Humoral Components (Complement)

- Total hemolytic complement assay (CH_{50})*
- Determination of C3 and C4 concentrations*
- Assay of individual components of classic and alternative pathways
- Functional measurement of alternative pathway
- Functional assay for C3a and C5a

ACQUIRED IMMUNITY

B Lymphocytes and Antibody Production

- Quantitation of serum IgG, IgA, and IgM*
- Measurement of specific antibodies after immunization*
- Isoagglutinin titer (anti-A and anti-B)*
- Determination of IgE and IgD concentrations
- Flow cytometric enumeration and analysis of B cell phenotype
- Tests of B cell-to-plasma cell maturation and antibody production in vitro

T Lymphocytes

- Total lymphocyte count and morphology*
- Delayed hypersensitivity skin tests to common antigens*
- Chest radiograph for thymic size*
- Proliferative responses to mitogens, antigens, and allogeneic cells
- Flow cytometric enumeration and analysis of T cell subsets
- Cytotoxicity assays
- Lymphokine production assays

---

*Considered one of the initial screening tests.

PART 2

Postnatal Bacterial Infections

Morven S. Edwards

NEONATAL SEPSIS

Despite the development of newer, more potent antimicrobial agents, infections are still an important cause of neonatal morbidity and mortality. Part 2 of this chapter focuses on bacterial infections; however, viral, fungal, and parasitic infections must be considered in the differential diagnosis of neonatal sepsis.

Incidence and Mortality

The term *sepsis neonatorum* is used to describe any systemic bacterial infection documented by a positive blood culture in the first month of life. Neonatal sepsis has distinct presentations based on the postnatal age at onset (Table 39-10): Early-onset sepsis occurs in the first 7 days of life and is acquired by vertical transmission from the mother. It usually has a fulminant onset with multisystem involvement, and has a higher case-fatality rate than late-onset sepsis (see Chapter 23). Late-onset sepsis usually is more insidious, but can have an acute onset. Late, late-onset sepsis occurs after 3 months of life and affects premature infants who are of very low birthweight (VLBW). Late, late-onset sepsis is often caused by *Candida* species or by commensal organisms such as coagulase-negative staphylococci (CONS), and often is associated with prolonged instrumentation, such as indwelling intravascular lines and endotracheal intubation. The incidence of neonatal sepsis ranges from 1 to 5 cases per 1000 live births. In the preantibiotic era, neonatal sepsis was almost uniformly fatal. Mortality rates decreased dramatically after the introduction of antimicrobial agents and with technological advances in neonatal care. Over the past two decades, the case-fatality rate has declined to approximately 5% to 10%.

Microbiology

The bacterial pathogens responsible for sepsis neonatorum tend to shift over time.[9] In the United States, gram-positive cocci, including group A *Streptococcus,* were common pathogens before the introduction of antibiotics, but this predominance shifted to gram-negative enteric bacilli after antimicrobial agents came into common use. In the 1950s and early 1960s, *Staphylococcus aureus* and *Escherichia coli* predominated as neonatal pathogens. In the late 1960s, group B *Streptococcus* (GBS) emerged as a perinatal pathogen, and it continues to be an important organism in newborn infections, as is *E. coli*. This predominance is reflected in the distribution of bacteria causing early-onset neonatal sepsis in active surveillance conducted over a multistate area during 1998-2000 (Table 39-11).[28] In neonates of VLBW with early-onset sepsis, GBS was the most frequent pathogen, followed by *E. coli* and *Haemophilus influenzae*.[65] An increase in the incidence of *E. coli* and a decrease in GBS has been noted over the last decade.[64]

TABLE 39–10 Characteristics of Neonatal Sepsis

	Early Onset (<7 Days)	Late Onset (≥7 Days to 3 Months)	Late, Late Onset (>3 Months)
Intrapartum complications	Often present	Usually absent	Varies
Transmission	Vertical; organism often acquired from mother's genital tract	Vertical or through postnatal environment	Usually postnatal environment
Clinical manifestations	Fulminant course, multisystem involvement, pneumonia common	Insidious or acute, focal infection, meningitis common	Insidious
Case-fatality rate	5%-20%	5%	Low

TABLE 39–11 Etiologic Agents in Neonatal Sepsis

Organism	No. (%)
Bacteria Causing Early-Onset Neonatal Sepsis*	
Group B *Streptococcus*	166 (41)

Total	1313 (100)

*Early onset, <7 days of age. Adapted from Hyde TB et al: Trends in incidence and antimicrobial resistance of early-onset sepsis: population-based surveillance in San Francisco and Atlanta, *Pediatrics* 110:690, 2002.

†Infants were all very low birthweight (<1500 g). Blood cultures were obtained after 72 hours of life. Adapted from Stoll BJ et al: Late-onset sepsis in very low birth weight neonates: the experience of the NICHD Neonatal Research Network, *Pediatrics* 110:285, 2002.

Other pathogens, including CONS, *Candida* species, and *S. aureus*, are more commonly etiologic agents in late-onset infection, as shown by data from a multicenter prospective registry in neonates with VLBW (see Table 39-11).[66] Community-acquired methicillin-resistant *S. aureus* (MRSA) strains have emerged as a significant cause of sepsis in neonates hospitalized in the neonatal intensive care unit since birth.[27] As history suggests, further changes in the etiologic agents of neonatal sepsis are likely and warrant continued observation.

Transmission

Infectious agents can be transmitted to a neonate in many ways. Transplacental transmission is well documented for congenital viral infections, but not for perinatal bacterial infections, with the exceptions of infections caused by *Treponema pallidum* and *Listeria monocytogenes*. Ascending intra-amniotic infection followed by aspiration of infected amniotic fluid can result in systemic neonatal infection, especially in the setting of prolonged rupture of membranes (ROM). Approximately 1% to 4% of neonates born to mothers with intra-amniotic infection develop systemic infection. Neonatal infection can also be acquired during vaginal delivery from bacteria colonizing the mother's lower genital tract. Inadequate hand washing by the nursery staff can promote the spread of microorganisms from an infected to an uninfected infant or from the hands of colonized caregivers to the newborn. The use of instrumentation, including endotracheal tubes, nasogastric feeding tubes, umbilical catheters, central venous catheters, and urinary catheters, also increases the risk of neonatal infection.

Early-onset infection is most often transmitted vertically by ascending amniotic fluid infection and by delivery through an infected or colonized birth canal. The pathogens that cause later onset disease can be acquired vertically in the peripartum period or horizontally from fomites in the environment or from colonized caregivers after delivery.

Risk Factors

MATERNAL RISK FACTORS

Maternal factors can influence the development of systemic bacterial infection in the neonate. (See also Chapter 23.) For reasons that remain unclear, the overall incidence of neonatal

GBS infections is higher among blacks than in other racial groups.[45] Maternal factors such as malnutrition and sexually transmitted diseases can also increase the risk of infection. The rates of prematurity and low birthweight, both of which predispose to neonatal infection, are inversely related to socioeconomic status. Maternal colonization with GBS is well documented as a risk factor for neonatal sepsis. Colonization during the third trimester in an uncomplicated pregnancy carries approximately a 1% risk of infection if acquisition by the neonate is not prevented by intrapartum antibiotic prophylaxis; this risk is increased if colonization is associated with prematurity, maternal fever, or prolonged ROM. Asymptomatic bacteriuria has been associated with premature birth. Colonization with genital mycoplasmas has been associated with low birthweight.

PERIPARTUM RISK FACTORS

Some peripartum factors associated with an increased risk of neonatal infection are untreated or incompletely treated focal infections of the mother (including urinary tract, vaginal, or cervical infections) and systemic infections, such as maternal septicemia or maternal fever without a focus. (See also Chapter 23.) Uncomplicated ROM lasting longer than 24 hours carries a 1% risk of neonatal sepsis above the baseline rate of 0.1% to 0.5%. The risk of infection increases fourfold if chorioamnionitis and prolonged ROM coexist. Prematurity and low birthweight are associated with an increased incidence of sepsis. In a population-based cohort study of neonatal GBS disease, attack rates of 5.99 per 1000, 2.51 per 1000, and 0.89 per 1000 live-born infants were noted for infants with birthweights of less than 1500 g, 1500 to 2500 g, and more than 2500 g.[56] Rates of first episode of late-onset infection per 1000 hospital days also decreased with increasing birthweight and gestational age, so that infants with a birthweight of 750 g or less had a fourfold higher rate than infants with a birthweight of 1000 g or more.[66]

Another peripartum risk factor is the use of fetal scalp electrodes. Deliveries using electronic fetal monitoring can be associated with subsequent development of neonatal scalp abscesses. Cephalhematomas rarely may be complicated by sepsis, meningitis, and osteomyelitis. Perinatal asphyxia, defined as a 5-minute Apgar score of less than 6, in the presence of prolonged ROM has been associated with an increased incidence of sepsis.

NEONATAL RISK FACTORS

Although no significant gender difference has been documented for infections acquired in utero, it was noted in the 1960s that male infants had a higher incidence of neonatal sepsis than female infants, possibly related to X-linked immunoregulatory genes. Immaturity of the immune system of the newborn host, as shown in Table 39-12, can also have a role in the predisposition to infection (see Part 1 of this chapter).[47] Metabolic disorders can predispose to infection. Among neonates of VLBW with late-onset sepsis, complications of prematurity associated with an increased rate of infection included mechanical ventilation, umbilical vessel catheterization, other vascular catheters, hyperalimentation, and duration of hospital stay.[66]

OTHER RISK FACTORS

It has been suggested that bottle feeding can predispose to infection. Prepared formulas lack several important biologic factors found in colostrum, such as bacterial agglutinins and iron-binding proteins, which have a local gastrointestinal protective effect against gram-negative enteric bacilli. Breast milk also contains immunoglobulins, macrophages, and lymphocytes, all of which play a role in immunologic defense.

TABLE 39–12 Host Responses to Bacterial Infection in Neonates

Component	Function	Status in Neonate	Clinical Significance
Complement	Opsonization, chemoattraction	Decreased complement components, especially in preterm infants	Decreased production of chemotactic factors; decreased opsonization of bacteria
Antibody	Opsonization, complement activation	IgG concentration decreased in preterm infants; term infants have higher concentration than adults; IgA absent from secretions	Lack of antibody to specific pathogens results in increased risk of infection; increased risk of mucosal colonization with potential pathogens
Neutrophil	Chemotaxis	Impaired migration; impaired binding to chemotactic factors	Decreased inflammatory response; inability to localize infection
	Phagocytosis	Normal with sufficient quantities of opsonin	
	Bacterial killing	Normal in healthy neonates; diminished in stressed neonates	
Monocyte	Chemotaxis	Decreased	Decreased inflammatory response
	Phagocytosis	Controversial	Uncertain
	Bacterial killing	Controversial	Uncertain

Adapted from Polin RA et al: Neonatal sepsis, *Adv Pediatr Infect Dis* 7:25, 1992.

Factors that may affect late-onset neonatal infection include prior antimicrobial use, prematurity, a high infant-to-nurse ratio in the neonatal intensive care unit, and the presence of foreign materials such as endotracheal tubes and ventriculoperitoneal shunts. Contaminated parenteral fluids, such as lipid emulsions, also have been associated with systemic infections.

Infants who acquire early-onset disease often have at least one major risk factor associated with pregnancy and delivery, such as prolonged ROM, preterm delivery, low birthweight, perinatal asphyxia, or maternal peripartum infection. By contrast, late-onset disease is seldom associated with obstetric complications.

Pathology

Histologic findings can be minimal in fulminant cases of neonatal sepsis.[58] When findings are present, they often reflect coexisting septic shock. Such findings may include renal medullary hemorrhage, renal cortical necrosis or acute tubular necrosis, adrenal cortical and medullary hemorrhage and necrosis, hepatic necrosis, intraventricular hemorrhage, and periventricular leukomalacia. Evidence of disseminated intravascular coagulation can be observed as well. In late-onset disease, pathologic changes consistent with the particular focal infection can be shown, including meningitis, pneumonia, hepatic abscesses, and arthritis or osteomyelitis. (Specific organ system infections are discussed later in the chapter.)

Diagnosis

SYMPTOMS AND SIGNS

The signs and symptoms of neonatal sepsis often are nonspecific. The temperature of an infant with sepsis may be elevated, depressed, or normal. Most, but not all, infants with sepsis have respiratory signs, including cyanosis or apnea. Other signs such as feeding difficulties or lethargy are nonspecific and may be subtle or insidious. A high index of suspicion is required to identify and evaluate at-risk infants.

CLINICAL MANIFESTATIONS

Bonadio and colleagues[10] evaluated prospectively a clinical observation scoring method for febrile infants younger than 2 months to determine its predictive value in distinguishing infectious from noninfectious illness. The variables examined were affect, feeding pattern, level of activity, level of alertness, respiratory status or effort, muscle tone, and peripheral perfusion. Inclusion criteria required that the infants had a rectal temperature of equal to or greater than 38°C (≥100.4°F) and had received no antibiotics within the previous 72 hours. Infants underwent a complete sepsis evaluation, including lumbar puncture for blood cell count, glucose and protein determinations, and Gram stain and culture; blood and urine cultures; and urinalysis from a catheterized sample.

The mean score for infants with serious bacterial infection (meningitis, sepsis, or urinary tract infection) was significantly higher than the mean score for infants with aseptic meningitis or for infants with negative cultures and normal cerebrospinal fluid (CSF). Affect, peripheral perfusion, and respiratory status were the variables that best differentiated infected from noninfected febrile infants. Two of the 29 infants with serious bacterial infections had normal observation scores; however, both had abnormal clinical or laboratory findings suggestive of infection. The negative predictive value of this scoring system was 96%. Although observational findings alone cannot replace the physical examination and laboratory studies, they are an important aspect of the evaluation of a febrile neonate.

Although medical attention often is sought for young infants with fever, it is not a finding specific for infection. Many noninfectious processes can result in pyrexia, including dehydration, drug withdrawal, and extensive hematomas. Palazzi and associates[44] came to the following conclusions pertaining to the presentation of neonatal sepsis:

- Temperature elevation in full-term infants is uncommon.
- Temperature elevation is infrequently associated with systemic infection when only a single elevated temperature occurs.
- Temperature elevation that is sustained longer than 1 hour is frequently associated with infection.
- Temperature elevation without other signs of infection is infrequent.
- The infant's temperature can be helpful in suggesting an infectious or noninfectious process if the trend of temperatures and the newborn's clinical status is considered, but a single reading should not be taken alone as an indication of infection.

Septic infants can present with neurologic findings such as seizures and full fontanelle even in the absence of meningitis. Gastrointestinal symptoms include hepatomegaly, abdominal distention, vomiting, diarrhea, guaiac-positive stools, and jaundice. Cutaneous manifestations other than jaundice can be present, but are uncommon findings in neonatal sepsis.

Focal infections can precede or accompany neonatal sepsis; these can include cellulitis, impetigo, soft tissue abscesses, omphalitis, conjunctivitis, otitis media, meningitis, and osteomyelitis. The presence of certain focal infections can suggest the causative agent, such as streptococci with cellulitis, staphylococci with abscesses, and *Pseudomonas aeruginosa* with necrotic skin lesions.

Complications of neonatal sepsis include metastatic foci of infection, disseminated intravascular coagulation, congestive heart failure, and shock.

DIFFERENTIAL DIAGNOSIS

Because the signs and symptoms of neonatal sepsis are nonspecific, noninfectious etiologies should be considered in the differential diagnosis. Sepsis with or without pneumonia can manifest as respiratory distress, transient tachypnea of the newborn, and meconium aspiration. Central nervous system (CNS) symptoms can be caused by sepsis and meningitis, and by intracranial hemorrhage, drug withdrawal, and inborn errors of metabolism. Intestinal obstruction, gastric perforation, and necrotizing enterocolitis can manifest with some of the gastrointestinal signs and symptoms seen with sepsis. Some nonbacterial infections, such as disseminated herpes simplex virus (HSV) infection, can be indistinguishable from bacterial sepsis and must be considered in the differential diagnosis.

MICROBIOLOGIC TESTS

Cultures

A definitive diagnosis of neonatal sepsis can be made only with a positive blood culture. Blood, urine, and CSF should be obtained from all infants suspected to have sepsis. The optimal number of blood cultures and volume of blood per culture have not been established for neonates. Obtaining more than one blood culture can be helpful in distinguishing blood culture contaminants from true pathogens. A minimum of 0.5 mL of blood per bottle is recommended. To avoid contamination, blood should not be obtained from a capillary stick or from umbilical catheters except perhaps immediately after insertion. Several manual and automated methods are available for detecting growth in the blood culture medium. Many new automated radiometric techniques can detect growth 8 hours after collection, and almost always within 24 to 48 hours after collection.

The yield from a urine culture is low in early-onset sepsis and most often reflects spread to the bladder in the setting of bacteremia. Urine for culture should be obtained in a sterile manner, such as by catheterization or suprapubic bladder aspiration, and sent for chemical and microscopic analyses and culture before antimicrobial therapy is started for infants with suspected late onset of infection.

CSF should be obtained before antibiotic administration and sent for blood cell count, differential, and chemistry determinations, and for Gram stain and culture (see “Meningitis,” later, and Appendix B for normal CSF indexes). Although controversial, some authorities believe that lumbar puncture may be postponed or excluded from the evaluation of an infant with suspected early-onset disease manifested by pneumonia. Meningitis accompanies sepsis, however, in approximately 10% of infants with early-onset disease and more often with late-onset disease. Meningitis cannot be diagnosed or excluded solely on the basis of symptoms, and blood cultures can be sterile in 10% to 15% of infants with early-onset meningitis and in one third of infants of VLBW with late-onset meningitis.[67]

Additional cultures should be obtained as indicated by clinical findings. Cultures of tracheal aspirates should be obtained in intubated neonates with a clinical picture suggestive of pneumonia, or when the quality and volume of the secretions change substantially and are consistent with a pneumonic process. Indiscriminate cultures of tracheal secretions can often be difficult to interpret, however. Aspirates or biopsy specimens of skin and soft tissue lesions can be sent for stains and cultures. If a bone or joint infection is suspected, evaluation of aspirated material is invaluable to establishing the diagnosis and determining susceptibility of the infecting pathogen. Stool cultures assist in the diagnosis of neonatal septicemia caused by enteric pathogens such as *Shigella, Salmonella,* and *Campylobacter,* but most often the bacteria recovered from stool cultures reflect gastrointestinal colonization, rather than infection. Cultures of gastric aspirates obtained on the first day of life reflect amniotic fluid infection and do not predict the development of neonatal infection.

Buffy Coat Examination

Leukocyte smears made from the buffy coat layer of centrifuged, anticoagulated blood can be stained with Gram stain and methylene blue or with acridine orange, then examined microscopically for intracellular bacteria. A positive buffy coat smear supports the diagnosis of sepsis and identifies the morphologic and Gram stain characteristics of the organism, but does not identify the infectious agent or include or exclude other foci of infection. Buffy coat examination is used infrequently since the advent of automated blood culture monitoring systems.

ANTIGEN DETECTION ASSAYS

Immunoassays that detect bacterial cell wall or capsule carbohydrate antigens in body fluids are an adjunct to diagnosis. Multiple studies have shown that antigen tests are an inappropriate substitute for properly performed bacterial cultures in the diagnosis of neonatal sepsis. With the available radiometric blood culture technology, rapid antigen testing is now infrequently required or indicated. In addition, these tests can provide results that are misleading. The only specimens recommended for testing with these devices are serum and CSF. A positive result should be taken to indicate the presence of antigen and not the presence of viable organisms.

OTHER LABORATORY TESTS

Leukocyte Counts

Many different aspects of the leukocyte count have been examined for their predictive value in diagnosing sepsis. Leukocytosis and leukopenia, defined as more than 20,000/mm^3 (leukocytosis) and less than 5000/mm^3 (leukopenia), have proven insensitive and nonspecific. A single leukocyte count obtained shortly after birth is not adequately sensitive for diagnosing sepsis.

Manroe and colleagues[37] established reference ranges for the absolute total neutrophil count, absolute total immature neutrophil count, and the ratio of immature to total neutrophils (I:T) for neonates during two time periods: the first 60 hours of life and from 60 hours to 28 days of life (Table 39-13). Mouzinho and associates,[40] from the same institution, observed that neonates with VLBW (weighing <1500 g and of ≤ 30 weeks' gestation) often had neutrophil indexes that did not fall within these ranges. Based on the results of combined retrospective and prospective study of infants with VLBW, the values for absolute total immature neutrophil count and I:T ratio were not significantly different from the ranges established by Manroe and colleagues,[37] but new absolute total neutrophil count ranges for infants with VLBW were proposed (Table 39-14). These ranges were based on small numbers of “normal, uninfected” neonates with VLBW. The latter reference range has higher specificity than the reference ranges of Manroe and colleagues,[37] suggesting that these ranges may be clinically useful in determining length of therapy in infants in whom cultures remain sterile.

The total neutrophil count has been examined for its value in predicting the presence of infection. Neutropenia, especially if it occurs in the first hours of life and is associated with respiratory distress, has a strong association with early-onset GBS sepsis. Many noninfectious processes are associated either with neutropenia or with neutrophilia

TABLE 39–13 Reference Ranges for Neutrophil (per mm^3) Indexes in Neonates

Index	Birth	12 Hours	24 Hours	48 Hours	72 Hours	≥120 Hours
ANC	1800-5400	7800-14,400	7200-12,600	4200-9000	1800-7000	1800-5400
INC	≤1120	≤1440	≤1280	<800	<500	<500
I:T	<0.16	<0.16	<0.13	<0.13	<0.13	<0.12

ANC, absolute neutrophil count (mature and immature forms); INC, immature neutrophil count (all neutrophils except segmented ones); I:T, ratio of INC divided by ANC.

Adapted from Manroe BL et al: The neonatal blood count in health and disease, I: reference values for neutrophilic cells, *J Pediatr* 95:89, 1979.

TABLE 39–14 Proposed Reference Range for Absolute Total Neutrophil Count in Infants with Very Low Birthweight*

	ABSOLUTE TOTAL NEUTROPHIL COUNT†	
Age	Minimum	Maximum
Birth	500	6000
18 h	2200	14,000
60 h	1100	8800
120 h	1100	5600

*Defined as ≤1500 g.

†Neutrophils/mm^3.

(Table 39-15 and Box 39-3).[71] Many infants with documented sepsis have normal total neutrophil counts at the time of the initial evaluation.

The absolute total immature neutrophil count, defined as the absolute number of all neutrophils excluding the segmented neutrophils, has also been extensively studied. All newborns, but especially premature infants, have a relatively large number of immature neutrophils in the first few days of life. Infected neonates can have an increase above the upper limits of normal in immature cells released from the bone marrow in response to infection, but this response is inconsistent and sometimes delayed, and is an insensitive marker for the early diagnosis of infection. It is unusual, however, for uninfected infants to have an elevated absolute total immature neutrophil count above the reference ranges; if such a finding is present, further evaluation for occult infection should be considered.

The I:T ratio has been investigated as an early predictor of sepsis. The maximal I:T ratio in uninfected neonates is 0.16 in the first 24 hours, decreasing to 0.12 by 60 hours. The upper limit of normal for neonates of 32 weeks' gestation or less is slightly higher, at 0.2. The test has a good negative predictive value, that is, there is a high likelihood that infection is absent if the I:T ratio is normal. Most infected neonates have an elevated I:T ratio some time during the infection, so repeatedly normal I:T ratios can be reassuring. The usefulness of this test is limited because many noninfectious processes, including prolonged induction with oxytocin, stressful labor, and even prolonged crying, are associated with increased I:T ratios.

Acute-Phase Reactants

The acute-phase response is a response of the body to infection or trauma clinically manifested by malaise, anorexia, fever, leukocytosis, negative nitrogen balance, and hepatic production of acute-phase proteins. Acute-phase reactants (APRs) are proteins produced by hepatocytes in response to inflammation. The inflammation can be secondary to infection, trauma, or other processes of cellular destruction. There are many different APRs, including CRP, fibrinogen, α_1-acid glycoprotein, α_1-antitrypsin, and elastase α_1-proteinase inhibitor. These APRs have different plasma half-lives and different incremental responses to inflammation. The method for the detection of APRs has improved with the development of rapid, automated, quantitative specific immunoassays. Numerous studies have evaluated APRs as early indicators of neonatal septicemia; an elevated APR does not distinguish between infectious and noninfectious causes of inflammation.

C-Reactive Protein

CRP is a globulin so named because it forms a precipitate in the presence of the C-polysaccharide of *Streptococcus pneumoniae*. It is believed to be a carrier protein involved in removing potentially toxic material. There is minimal transplacental passage of maternal CRP, and concentrations are unaffected by gestational age. Current methods are fully automated and provide a quantitative assessment of protein concentration. Normal concentrations in neonates are assay-dependent, but the upper limit of normal usually is 1 mg/dL. CRP is significantly elevated at the time of the initial evaluation in 50% to 90% of infants with systemic bacterial infections, but CRP has a low positive predictive value and should not be used alone to diagnose sepsis.

An increasing CRP value is usually detectable within 6 to 18 hours, and the peak CRP is seen at 8 to 60 hours after onset of an inflammatory process. The serum half-life is short, so the CRP usually declines to a normal concentration within 5 to 10 days in most infants with infection who have a favorable response to therapy. Serial determinations of CRP are valuable in excluding serious infections. The very high negative predictive value of several normal CRP values in sequence can allow for early discontinuation of empirical antibiotics in selected clinical settings. Nonbacterial infections can elicit a variable CRP response, with normal values in culture-positive viral meningitis and increased values in minor viral infections. Noninfectious processes, including

meconium aspiration pneumonitis, can have an elevated CRP 10 times the normal concentration.

Erythrocyte Sedimentation Rate

The erythrocyte sedimentation rate (ESR) is not a direct measure of an APR, but rather reflects changes in many serum protein APRs. A micro-ESR has been developed for use in infants. An approximation of the maximal normal rate in the first 2 weeks of life can be obtained by adding 3 to the age of the newborn in days. Beyond 2 weeks of life, the maximal rate varies between 10 and 20 mm/h. Owing to interlaboratory variation, each laboratory must develop its own reference range. The ESR is limited in that other factors unrelated to inflammation (e.g., anemia, hyperglobulinemia) can affect the rate. Micro-ESR values vary inversely with the hematocrit, but are affected little, if at all, by birthweight or gestational age. Slightly elevated micro-ESR values can occur with superficial infections and with noninfectious processes, including asphyxia, aspiration pneumonia, and respiratory distress syndrome. Markedly elevated values in the absence of infection are unusual, but have been observed with Coombs-positive hemolytic disease and physiologic hyperbilirubinemia. The long delay after onset of the inflammatory process before the peak ESR is reached and its long half-life render it of limited usefulness in monitoring the progress of bacterial infections in neonates.

Fibrinogen

Plasma fibrinogen concentrations are known to increase in association with infection, although some factors can result in a low fibrinogen level despite severe infection, including disseminated intravascular coagulation, exchange transfusion, and respiratory distress syndrome. Measurement of fibrinogen concentrations is not useful in the early diagnosis of infection because there is a large overlap in values between infected and healthy infants.

Fibronectin

Fibronectin is a multifunctional, high-molecular-weight glycoprotein produced primarily by the liver and endothelial cells, and widely distributed in the body, including in plasma and body fluids, on cell surfaces, and in the extracellular matrix. Fibronectin is involved in hemostasis, vascular integrity, and wound healing. It is important in embryogenesis, directing cell migration, proliferation, and differentiation. Fibronectin aids in the immune response by augmenting macrophage and neutrophil phagocytosis and acting as a nonspecific opsonin for the reticuloendothelial system. The plasma fibronectin concentration varies with age. In healthy neonates, it is approximately half that found in adults, whereas healthy premature infants have approximately one third of the amount in normal adults. After birth, the plasma concentration gradually increases, reaching adult values by 2 months of age. Fibronectin has been found to be decreased in neonates with infection and in neonates with asphyxia, respiratory distress syndrome, and bronchopulmonary dysplasia.

Cytokines

Cytokines such as IL-1β, IL-6, IL-8, TNFα, and others are endogenous mediators of the immune response to inflammation. There is evidence that measuring cytokine concentrations can be helpful in the early diagnosis of neonatal sepsis, but the study design employed and the method for each assay can affect the reported performance.[52] In some reports, such as that of Girardin and colleagues,[22] assay performance is excellent. These investigators found that 8 of 9 infants with systemic infection, but only 1 of 60 uninfected infants, had elevated serum TNFα. Confounding effects of maternal complications can affect findings, however. IL-6 and IL-8 can be elevated in infants with sepsis and in the setting of chorioamnionitis. Timing can have an impact on assay performance. Buck and coworkers[12] evaluated prospectively the use of IL-6 and CRP measurements in the diagnosis of early-onset sepsis in 222 neonates. Elevated IL-6 concentrations were observed in 73% of newborns with culture-positive infection and in 87% of infants with a clinical diagnosis of sepsis but negative cultures. Most newborns (78%) without evidence of infection had normal IL-6 concentrations. Of the infected newborns with normal IL-6 concentrations, 55% had elevated CRP measurements, suggesting that the peak IL-6 concentration was missed because of its short half-life.

Many investigators have evaluated colony-stimulating factors in the neonatal period. Data are conflicting, but suggest that concentrations of granulocyte colony-stimulating factors vary with gestational age and are influenced by mode of delivery, nutritional status, maternal hypertension, maternal glucocorticoid therapy, and infection.[4] A peak in granulocyte colony-stimulating factor concentration was observed approximately 7 hours after birth in healthy newborns, with a corresponding increase in the total neutrophil count 7 to 12 hours after birth. Infected newborns had a much higher peak concentration at 7 hours than uninfected infants.

Screening Panels

Excluding cultures, none of the previously mentioned tests, when used alone, is sensitive or specific enough to diagnose or exclude neonatal sepsis reliably. Numerous investigators have evaluated the predictive values of panels of tests for diagnosing sepsis. (Table 39-16 presents definitions of terms used in evaluating such tests.)

Krediet and colleagues[32] measured daily CRP values and I:T ratios in all newborns admitted to the nursery—185 patients during the first 4 days of life and 107 infants after the fourth day of life. A sepsis workup, including cultures, complete blood count, and radiologic studies, was performed as clinically indicated. For early-onset disease, the positive predictive value of either test alone was 18% to 23%, and the negative predictive value was 95% to 98%. When the tests were used together, the positive predictive value increased to 32%, and the negative predictive value decreased to 95%. For late-onset sepsis, the positive predictive value and negative predictive value for the tests, when used alone, ranged from 59% to 63% and 90% to 94%. When the tests were used together to screen for late-onset infection, the positive predictive value increased to 65%, and the negative predictive value decreased to 88%. These researchers concluded that a screening panel comprising CRP and the I:T ratio had limited value.

Tegtmeyer and coworkers[69] assessed a screening panel in 74 infected neonates. Their panel comprised CRP, I:T ratio, granulocyte count, and Eα_1-PI. The sensitivity of each test alone ranged from 36% to 70% except for Eα_1-PI, which

TABLE 39–16 Terms Used for Analyzing Accuracy and Reliability of Tests

Term	Definition
Sensitivity	Percentage of patients with infection who have an abnormal test result
Specificity	Percentage of patients without infection who have a normal test result
Positive predictive value	If test result is abnormal, percentage of patients with infection
Negative predictive value	If test result is normal, percentage of patients with no infection

From Weinberg GA et al: Laboratory aids for diagnosis of neonatal sepsis. In Remington JS et al, editors: *Infectious diseases of the fetus and newborn infant,* 6th ed. Philadelphia, Saunders, 2006, p 1208.

ranged from 87% (early-onset sepsis) to 100% (late-onset disease). When all the tests were used together, the sensitivity increased to 100%. Because the authors assessed only infected infants, they were unable to determine the specificity or predictive accuracy of their screening panel.

Philip and colleagues[46] evaluated the predictive accuracy of a three-part screen (Eα_1-PI, I:T ratio, and CRP) in more than 300 infected and uninfected infants admitted to the neonatal intensive care unit. When used alone, Eα_1-PI was more sensitive than the other two tests for diagnosing sepsis, but had a lower positive predictive value. When the three tests were used as a panel, the sensitivity was 23%, the specificity was 99.7%, the positive predictive value was 87.6%, and the negative predictive value was 99.7%. The use of screening panels does not significantly improve the positive predictive accuracy; however, the predictive accuracy of a negative panel often increases to 98% to 100%, and a panel with this accuracy of performance in excluding disease can provide useful information.

Treatment

EMPIRICAL ANTIMICROBIAL THERAPY

Although signs and symptoms of neonatal sepsis are often subtle and nonspecific, when the clinical diagnosis is obvious, the infant is often critically ill. Empirical antimicrobial therapy should be instituted immediately after obtaining samples for culture rather than waiting for the culture results. The choice of therapy should be based on several factors, including the timing and setting of the disease (e.g., early onset, late onset community acquired, health care associated late or very late onset), the microorganisms most frequently encountered, the susceptibility profiles for those organisms, the site of the suspected infection and the penetration of the specific antibiotic to that site, and the safety of the antibiotic. Caregivers should be aware of the susceptibility profiles for the most common neonatal pathogens isolated in their community and in their neonatal unit. Nonbacterial infectious etiologies must be considered in the differential diagnosis and, if deemed a significant possibility, appropriate antiviral or antifungal therapy must be started in addition to antibiotic therapy.

For early-onset disease in the United States, the antimicrobial regimen should provide coverage against GBS, *E. coli* and other gram-negative enteric bacilli, and *L. monocytogenes*. The combination of ampicillin and an aminoglycoside is frequently used. *Listeria* and GBS are uniformly susceptible to ampicillin, whereas the susceptibility of *E. coli* to ampicillin is less reliable. The aminoglycoside provides coverage against most gram-negative enteric bacilli and, with gentamicin specifically, has been found to act synergistically with ampicillin against GBS and *Listeria* organisms in vitro and in animal models. The choice of aminoglycoside should be based on susceptibility patterns for gram-negative enteric bacilli in the community. Gentamicin is used most frequently, with tobramycin and amikacin reserved for treatment of multidrug-resistant bacteria. If meningitis is suspected, especially gram-negative bacillary meningitis, many clinicians add or replace the aminoglycoside with the third-generation cephalosporin, cefotaxime, for better CNS penetration.

Empirical therapy for late-onset disease acquired in the community should provide coverage for the same neonatal pathogens discussed earlier and for potential community-acquired pathogens, such as *S. pneumoniae* and *Neisseria meningitidis*. Because meningitis frequently is a component of late-onset sepsis, antibiotics with good CNS penetration should be selected. Ampicillin and a third-generation cephalosporin (e.g., cefotaxime) are commonly recommended.

Health care–associated late-onset disease can be caused by the usual neonatal pathogens, but also by coagulase negative staphyloccus (CONS), enterococci, gram-negative enteric bacilli (including drug-resistant strains), and fungi. Therapy depends on the presence of risk factors for commensal organisms such as CONS (use of catheters or shunts) and the susceptibility profiles for common nosocomial pathogens isolated from the nursery. Virtually all staphylococci produce penicillinase and are resistant to ampicillin and penicillin. Vancomycin and gentamicin are commonly used for initial therapy. Vancomycin generally is active against all staphylococcal species, streptococci, and most enterococci, whereas the spectrum of activity of a penicillinase-resistant penicillin includes streptococci and only the methicillin-susceptible strains of CONS and *S. aureus*. Cefotaxime or ceftriaxone can be included when gram-negative meningitis is a concern. Cefotaxime does not have activity against *L. monocytogenes*, enterococci, or *Pseudomonas* species. Ceftazidime with an aminoglycoside should be used if *Pseudomonas* infection is suspected. Meropenem can be required when multidrug-resistant enteric gram-negative organisms are isolated. Many other combinations of antimicrobial agents can be effective therapy for nosocomial late-onset sepsis; however, it is prudent to use agents that have proven with experience to be safe.

The risks and benefits should be considered thoroughly if routine use of third-generation cephalosporins for late-onset disease is contemplated. One disadvantage is an increased risk for development of gastrointestinal colonization and perhaps subsequent infection with fungi and drug-resistant bacteria. With ceftriaxone, in particular, there is a theoretical risk of bilirubin displacement from albumin because of the drug's high protein-binding capacity. There are no clinical data to substantiate this effect in neonates. These cephalosporins are safe and effective against many of the common neonatal pathogens, and there is extensive experience with cefotaxime use during the neonatal period. Because third-generation cephalosporins do not cause the dose-related toxicities seen with agents such as aminoglycosides, monitoring of serum concentrations is unnecessary. Empirical therapy usually may be narrowed to one drug when final culture identification and susceptibility results are available.

The dosage and frequency of administration of antimicrobial agents vary with the newborn's gestational age, postnatal age, birthweight, and status of hepatic and renal function. Recommendations for antibiotic use in neonates are given in Tables 39-17 through 39-19 and in Appendix A.[41] These are guidelines only; specific doses and intervals may change frequently, especially in critically ill infants. Serum concentrations of aminoglycosides and, in some circumstances, vancomycin, should be monitored to ensure therapeutic efficacy while minimizing toxicity. The duration of therapy depends on the site of infection (see later).

TABLE 39–17 Recommended Dosage Schedule for Antimicrobial Agents Frequently Used to Treat Neonatal Sepsis

		DOSAGE (mg/kg/d) AND INTERVALS OF ADMINISTRATION			
		BODY WEIGHT ≤2000 g		BODY WEIGHT >2000 g	
Antibiotic	**Route**	**0-7 Days**	**>7 Days**	**0-7 Days**	**>7 Days**
Ampicillin	IV, IM	100 div q12h	150 div q8h	150 div q8h	200 div q6h
Aztreonam	IV, IM	60 div q12h	90 div q8h	90 div q8h	120 div q6h
Cefotaxime	IV, IM	100 div q12h	150 div q8h	100 div q12h	150 div q8h
Ceftazidime	IV, IM	100 div q12h	150 div q8h	150 div q8h	150 div q8h
Ceftriaxone	IV, IM	50 once daily	50 once daily	50 once daily	75 once daily
Clindamycin	IV, IM, PO	10 div q12h	15 div q8h	15 div q8h	20 div q6h

TABLE 39–18 Recommended Dosage Schedule for Aminoglycosides and Vancomycin in the Treatment of Neonatal Sepsis

		DOSAGE FOR WEEKS' GESTATION OR POSTCONCEPTIONAL AGE		
Antibiotic	**Route**	**<30**	**30-37**	**>37**
Amikacin[*]				
≤7 days	IV, IM	15 mg/kg 24h	15 mg/kg q18h	15 mg/kg q12h
>7 days		15 mg/kg q18h	15 mg/kg q12h	15 mg/kg q8h
Tobramycin[†‡]				
≤7 days	IV, IM	3 mg/kg q24h	3 mg/kg q18h	2.5 mg/kg q12h
>7 days		3 mg/kg q18h	2.5 mg/kg q12h	2.5 mg/kg q8h
Vancomycin[§]				
≤7 days	IV	20 mg/kg q24h	15 mg/kg q18h	15 mg/kg q12h
>7 days		20 mg/kg q18h	15 mg/kg q12h	15 mg/kg q8h

[*] Desired serum concentrations: peak 20-40 μg/mL, trough <10 μg/mL.

[†] Desired serum concentrations: peak 5-10 μg/mL, trough ≤2 μg/mL.

[‡] Gentamicin dosing: for <35 weeks' postmenstrual age, 3 mg/kg/dose q24h; for ≥35 weeks' postmenstrual age, 4 mg/kg/dose q24h.

[§] Desired serum concentrations: peak 20-40 μg/mL, trough <15 μg/mL.

TABLE 39–19 Indications, Pharmacology, and Toxicity of Antibiotics Commonly Used in Newborns

Antibiotic	Indications	Pharmacology	Toxicity	Comments
Amikacin	Aerobic gram-negative infections; use should be limited to treatment of gentamicin-resistant organisms	Renal excretion; activity in CSF low; not absorbed from GI tract	Possible ototoxicity, nephrotoxicity, and neuromuscular blockade	Toxicity rare if appropriate dosage is used, and blood concentration is monitored
Ampicillin	Initial treatment of sepsis and meningitis; gram-positive organisms except staphylococci; gram-negative organisms if susceptible (*Salmonella, Shigella, Haemophilus, Escherichia coli*)	Renal excretion	Seizures when high dosages are given	
Cefotaxime	Sepsis, meningitis caused by susceptible gram-negative organisms	Primarily renal excretion; good penetration into CSF		Active against streptococci; routine use can result in emergence of resistant gram-negative organisms
Ceftazidime	Can be used in combination with aminoglycoside for treatment of *Pseudomonas* infection	Renal excretion; penetrates blood-brain barrier		
Ceftriaxone	Sepsis, meningitis, soft tissue and bone/joint infections caused by susceptible organisms; not effective against staphylococci, *Listeria* species, enterococci, or *Pseudomonas* species	30%-65% excreted by kidneys, the remainder excreted in bile; penetrates blood-brain barrier	Potential gallbladder sludging	May displace bilirubin from albumin-binding sites in neonates
Clindamycin	Treatment of susceptible anaerobic infections		Pseudomembranous colitis in older children, but rare in neonates	
Chloramphenicol	Treatment of infections caused by bacteria resistant to all other antibiotics (e.g., *Salmonella* species)	Metabolized by liver, small amount excreted unchanged in urine; good penetration through blood-brain barrier	Gray baby syndrome (vasomotor collapse) related to immature hepatic function and associated with elevated concentrations of unconjugated chloramphenicol	Dose-related reversible bone marrow suppression; idiopathic irreversible aplastic anemia (rare); monitoring of blood concentration mandatory
Erythromycin	*Chlamydia, Pertussis* species, minor staphylococcal or streptococcal skin infections	Excreted in urine, stool, and biliary system; crosses blood-brain barrier poorly	No significant toxicity	

Continued

TABLE 39–19 Indications, Pharmacology, and Toxicity of Antibiotics Commonly Used in Newborns—cont'd

Antibiotic	Indications	Pharmacology	Toxicity	Comments
Gentamicin	Can be used for initial treatment of neonatal sepsis; not effective alone, but can be synergistic when used with ampicillin against group B streptococci, enterococci, and *Listeria* species	Renal excretion; activity low in CSF; not absorbed from GI tract in normal host	Possible ototoxicity, nephrotoxicity, and neuromuscular blockade	Toxicity rare if appropriate dosage is used, and blood concentrations are monitored
Nafcillin, oxacillin	Penicillin-resistant *Staphylococcus aureus* infections; active against streptococci, but not a first-line agent	Excretion is renal and hepatic for nafcillin and oxacillin; nafcillin and oxacillin are highly protein bound		
Neomycin	Bacterial diarrhea, enteropathogenic *E. coli*	Not absorbed by GI tract	Ototoxic, nephrotoxic if absorbed	Do not use parenterally
Penicillin G	Most streptococci, *Treponema pallidum*, *Bacteroides* species (except *Bacteroides fragilis*), *Neisseria meningitidis*	Renal excretion; fair penetration of inflamed meninges		Can be used to treat infections caused by susceptible organisms
Streptomycin	*Mycobacterium tuberculosis*	Renal excretion	Vestibular and auditory damage, nephrotoxicity	Must be given IM
Ticarcillin	Expanded gram-negative activity; can be used to treat susceptible *Pseudomonas* infections	Renal excretion	Platelet dysfunction	Can be associated with hypernatremia and hypokalemia; electrolytes are monitored
Tobramycin	Broad coverage of gram-negative organisms	Renal excretion; low activity in CSF	Possible ototoxicity and nephrotoxicity	Blood concentrations are monitored
Vancomycin	Effective against coagulase-negative staphylococci, methicillin-resistant *S. aureus*; most gram-positive aerobic organisms are susceptible	Renal excretion	Possible ototoxicity; previous preparations associated with nephrotoxicity	Flushing or hypotension may result from rapid infusion
Sulfonamides	Contraindicated in newborns		Displaces bilirubin from albumin-binding sites	
Tetracyclines	Contraindicated in newborns		Permanent discoloration of teeth, enamel hypoplasia; inhibits bone growth in premature infants	

CSF, cerebrospinal fluid; GI, gastrointestinal.

SUPPORTIVE THERAPY

Although appropriate antimicrobial therapy is crucial, supportive care is equally important. Ventilatory support may be necessary, particularly for infants with fulminant early-onset disease. Intravenous hydration and perhaps parenteral nutrition, with close monitoring of electrolytes and glucose, should be considered. Septic shock, if present, should be treated appropriately with fluids and inotropes as indicated by the clinical situation.

IMMUNOTHERAPY

The newborn's immune system is compromised in many aspects, including the neutrophil's chemotactic response to pathogens, T cell production of proinflammatory cytokines, and functional complement activity (see Part 1 of this chapter). Preterm infants are compromised further by hypogammaglobulinemia because significant transfer of maternal IgG does not begin until 32 to 34 weeks' gestation. Even term infants can lack specific antibodies to the most common pathogens in early-onset neonatal infections because most adults have low concentrations of antibody against GBS and *E. coli*. With the increased risk of overwhelming bacterial infection in preterm neonates, researchers have studied the effect of intravenous immune globulin (IVIG) in preventing and treating neonatal infections.

Intravenous Immune Globulin

There have been numerous studies evaluating IVIG for treatment of infected neonates. A beneficial effect from IVIG and appropriate antibiotics was observed in several studies compared with antibiotics used alone for the treatment of sepsis. These studies were limited, however, by small numbers of patients, nonblinded investigators, lack of a placebo control, or lack of bacteria-specific analysis of the IVIG preparation used. Meta-analysis of studies of IVIG for the treatment of neonates with sepsis showed a significant decrease in the mortality rate compared with standard therapies.[30] Further studies are warranted before IVIG use in infections can be recommended as routine therapy.

Other Agents in Development

Other agents that may be beneficial in the treatment of neonatal infections include human monoclonal IgM antibodies and pathogen-specific hyperimmune globulins. An intravenous *S. aureus* polyclonal immune globulin was well tolerated in VLBW infants, but further investigation is needed to assess efficacy.[5] Fibronectin administration may be useful in the prevention and treatment of neonatal sepsis because of its multifunctional roles, including nonspecific opsonization that aids in clearing debris in the reticuloendothelial system, augmentation of phagocytic activity, and hemostasis. Fibronectin has been used in adults as a topical agent to improve wound healing with persistent corneal ulcerations and intravenously in uncontrolled studies of patients with multiorgan system failure. Preliminary results seem encouraging, but large, prospective, controlled studies are required before any recommendations about its use can be made. Early postnatal prophylactic granulocyte-macrophage colony-stimulating factor corrected neutropenia in a single-blind, multicenter, randomized controlled trial in preterm infants, but it did not reduce sepsis or improve survival and short-term outcomes.[13]

PREVENTION

Intrapartum antibiotic prophylaxis (IAP) for prevention of early-onset GBS disease has been in widespread use since 1996. The guidelines issued in 1996 recommended screening of pregnant women for GBS colonization either by lower vaginal and rectal cultures obtained at 35 to 37 weeks' gestation or by assessing clinical risk factors to identify candidates for IAP. A comparison of the two prevention strategies showed that culture-based screening was 50% more effective than a risk-based strategy in preventing early-onset disease in neonates.[55] An 80% reduction in early-onset GBS disease, to approximately 0.3 to 0.4 per 1000 live births, has been achieved in the IAP era.[45] The 2002 revised guidelines from the Centers for Disease Control and Prevention (CDC) recommend that all pregnant women be screened during each pregnancy for GBS carriage. Lower vaginal and rectal cultures obtained at 35 to 37 weeks' gestation should be placed in a non-nutritive transport medium, incubated in selective broth medium, and subcultured into 5% sheep blood agar for isolation of GBS.

All pregnant women identified as GBS carriers should receive IAP at the time of labor or ROM. Penicillin (5 million U initially and then 2.5 million U every 4 hours until delivery) is recommended.[15] Ampicillin (2 g initially and then 1 g every 4 hours until delivery) is an acceptable alternative. Penicillin-allergic women who are not at high risk for anaphylaxis should receive cefazolin (2 g initially and 1 g every 8 hours until delivery). Vancomycin is recommended for women with a high risk for anaphylaxis. Because of increasing rates of resistance, clindamycin and erythromycin are less effective as alternative agents. These drugs should be reserved for women with risk of anaphylaxis in whom testing has indicated that the isolates are susceptible.

Delivery of a previous infant with invasive disease and GBS bacteriuria is always an indication for IAP. IAP is not indicated for planned cesarean section before ROM and onset of labor. Risk factors (labor onset or ROM before 37 weeks' gestation, ROM $\geq$18 hours before delivery, or intrapartum fever) should be used only when the results of cultures are unknown at the onset of labor. An algorithm for IAP for women with threatened preterm delivery is included in the current recommendations.[15]

The management of infants born to women receiving IAP depends on the infant's status at birth, the duration of prophylaxis, and the gestational age of the infant. If a woman receives IAP for suspected chorioamnionitis, her infant should have a full diagnostic evaluation and empirical therapy pending culture results based on the infant's exposure to established infection. Symptomatic infants should undergo full diagnostic evaluation and empirical therapy. A lumbar puncture, if feasible, should be performed. Limited evaluation consisting of complete blood count with differential and blood culture and observation for at least 48 hours is indicated for asymptomatic infants of less than 35 weeks' gestation and for infants whose mothers received chemoprophylaxis for less than 4 hours before delivery. Observation is appropriate for asymptomatic infants of at least 35 weeks' gestation whose mothers received chemoprophylaxis at least 4 hours before delivery.

Exposure to antibiotics during pregnancy has not changed the clinical spectrum of GBS disease or the onset of clinical signs of infection within 24 hours of birth for term infants with early-onset GBS infection.[11] In reports that document increases in non-GBS sepsis, the increase has occurred only in infants born prematurely or with low birthweight. Surveillance in two cities found stable rates of sepsis caused by other organisms, but an increase in ampicillin-resistant *E. coli* among preterm but not term infants.[28] Intrapartum ampicillin exposure has been shown to be an independent risk factor for ampicillin-resistant, early-onset sepsis.[8] These trends indicate the importance of ongoing surveillance. A comprehensive program for prevention of neonatal bacterial infections awaits the development and licensure of vaccines, some of which are now under testing, and of strategies to prevent premature delivery.

INFECTION OF ORGAN SYSTEMS

Meningitis

INCIDENCE

The contemporary incidence of bacterial meningitis in neonates is approximately 0.3 per 1000 live births. Bacterial meningitis can occur in 15% of neonates with bacteremia. For GBS, a higher proportion of late-onset cases than of early-onset cases identified from 2003-2005 manifested as meningitis (27% versus 7%; $P < .001$).[45] Low birthweight (<2500 g) and preterm birth (<37 weeks of gestation) are associated with an increased risk for neonatal meningitis. Meningitis has a predilection for young age; the incidence is higher in the first month of life than at any other age.

ETIOLOGY

The causative agents for neonatal meningitis generally mirror the causative agents associated with neonatal sepsis (see Table 39-11). One review of 101 infants with a gestational age of at least 35 weeks found that GBS accounted for 50%, *E. coli* accounted for 25%, other enteric gram-negative rods accounted for 8%, and *Listeria* accounted for 6% of cases. Among the remaining patients, *S. pneumoniae,* group A *Streptococcus,* and nontypable *H. influenzae* each accounted for less than 5% of cases.[31] Among premature infants, and especially VLBW infants, *Enterococcus,* CONS, and α-hemolytic streptococci also must be considered potential pathogens.

PATHOGENESIS

There are three mechanisms by which the meninges can become infected: (1) primary sepsis with hematogenous seeding; (2) focal infection outside the CNS, with either secondary bacteremia and resulting hematogenous dissemination or direct extension (e.g., from an infected sinus); and (3) direct inoculation after head trauma or neurosurgery, or from an open congenital defect, such as myelomeningocele or dermal sinus. The most common mechanism in neonates is hematogenous spread associated with a primary bacteremia, so the perinatal risk factors that predispose an infant to neonatal sepsis also influence the risk of acquiring meningitis. Certain microbial factors are associated with increased risk of meningeal invasion. Despite the presence of more than 100 different capsular polysaccharide K antigens in *E. coli*, the K_1 capsular type is isolated in 70% of neonates with meningitis. Similarly, type III strains are responsible for 70% of all early-onset or late-onset GBS meningitis. The IVb serotype of *L. monocytogenes* is more frequently isolated in late-onset *Listeria* meningitis than are the other serotypes.

PATHOLOGY

Berman and Banker[7] reviewed clinical data from 29 neonates with bacterial meningitis, including 25 with postmortem examinations. All but two of the infections were caused by gram-negative enteric bacilli. The pathologic characteristics closely resembled characteristics found in older infants and children. In the acute stage, brain edema was prominent, but had not led to herniation in any of the infants. A subarachnoid exudate located at the base of the brain or evenly distributed over the cerebral hemispheres or, less commonly, isolated to the convexity was observed. In the acute stage of meningitis, a neutrophilic exudate predominated, which progressed to a mononuclear exudate by the chronic stage. Ventriculitis, resulting from destruction of the epithelial lining of the ventricles after inflammatory cell infiltration, was common. Vasculitis and radiculopathy caused by inflammatory cell infiltration were seen. Parenchymal changes included gliosis, encephalopathy, and infarction. Microglial proliferation was observed in the cerebral and cerebellar hemispheres, in the marginal white matter of the spinal cord and brainstem, and in the ependymal lining of the fourth ventricle and aqueduct. This proliferation sometimes resulted in narrowing or obliteration of the foramen of Luschka and aqueduct of Sylvius. A diffuse encephalopathy of uncertain etiology occasionally was present, believed to be metabolic in origin.

Many of the known pathologic sequelae of meningitis were shown at autopsy. Hydrocephalus was observed in 14 of the 25 infants. Communicating hydrocephalus, defined as normal flow of CSF from the lateral ventricles through the fourth ventricle, but obstruction of flow from impaired resorption in the arachnoid villi, was noted in nine infants. Five infants had noncommunicating hydrocephalus, defined as obstructed CSF flow at the level of the aqueduct of Sylvius or the foramina secondary to purulent exudate or gliosis. Hydrocephalus ex vacuo also can be observed when the ventricles are enlarged owing to loss of cerebral cortical tissue and secondary white matter degeneration as a result of encephalopathy; however, CSF flow is not impeded. Infants with ventriculitis can have prolonged symptoms with delayed sterilization of CSF. Thrombosis and cerebral infarcts can develop as a result of the vasculitis. Brain abscesses and subdural effusions were not observed in the series by Berman and Banker.[7] When brain abscess formation does occur, it tends to be associated with certain organisms, such as *Citrobacter koseri* (previously *Citrobacter diversus*) or *Enterobacter sakazakii.*

CLINICAL MANIFESTATIONS

The early signs and symptoms of neonatal meningitis are nonspecific. The signs most frequently observed include lethargy, reluctance to feed, emesis, respiratory distress, irritability, and temperature instability. Signs suggestive of a CNS process are less commonly observed in neonates with meningitis than in older children. A review of the clinical signs of bacterial meningitis in 255 newborns from six medical centers found that 40% had convulsions, 28% had a full or bulging fontanelle, and only 15% had nuchal rigidity.[44] In preterm infants, the signs and symptoms can be subtle. Because of the high mortality rate and risk of serious sequelae in survivors, and the nonspecificity of signs and symptoms in meningitis, the clinician must have a high index of suspicion when evaluating ill neonates.

DIAGNOSIS

The diagnosis of neonatal meningitis requires growth of the microorganism from the CSF. A presumptive diagnosis can be made when the CSF indexes suggest a bacterial process, and a pathogen is isolated from a blood culture. A thorough evaluation of CSF for the presence of infection includes bacterial culture and Gram-stained smear, cell count with leukocyte differential, and glucose and total protein determinations. Normal values for CSF indexes in the neonate are different from normal values in older infants or children and can be difficult to interpret if the age of the patient is not considered. As a guide to interpretation, a CSF leukocyte count exceeding 20 to 30/mm^3 is a threshold for the presence of meningeal inflammation and should warrant consideration of meningitis as a possible diagnosis.

Sarff and colleagues[53] analyzed the CSF findings in 117 neonates with signs and symptoms suggestive of infection, but with sterile CSF cultures and no laboratory evidence consistent with a viral or bacterial process. These neonates had obstetric or neonatal factors that increased their risk for infection, including maternal toxemia, prolonged ROM, chorioamnionitis, maternal fever, unexplained jaundice, and prematurity. The CSF protein and glucose determinations and leukocyte counts in these neonates were elevated compared with older infants and children (Table 39-20). The CSF cell count was observed to decrease during the first week of life in term infants, but to increase in preterm infants. An alteration in blood-brain barrier permeability was cited as a potential mechanism for these findings.

Rodriguez and colleagues[50] evaluated CSF indexes during the first 12 weeks of life in high-risk infants with VLBW. These infants had sterile CSF bacterial cultures, weighed less than 1500 g at birth with weights appropriate for gestational age, and had no ultrasound evidence of intracranial hemorrhage. The CSF values were analyzed by chronologic age of the infant and by postconceptual age, defined by the authors as gestational age plus the chronologic postnatal age. The CSF glucose and protein determinations were higher in infants 26 to 28 weeks of age than in other age groups (Table 39-21; see also Appendix B).

CSF findings in 135 neonates with bacterial infections, including 98 with gram-negative bacillary meningitis, 21 with GBS meningitis, and 16 with septicemia without meningitis, were analyzed by Sarff and colleagues[53] using the reference ranges derived from 117 high-risk infants without documented infection. Only 4% of neonates with gram-negative bacillary meningitis had CSF leukocyte counts within the normal range, whereas 23% and 15% had normal protein and normal CSF and blood glucose determinations. *E. coli* was isolated from a CSF sample with normal cell count, glucose, and protein determinations in one infant. The indexes on repeat CSF evaluation from this patient were consistent with bacterial meningitis. Because CSF may be obtained early in the course of meningitis, before the inflammatory process is evident, normal CSF parameters do not exclude a diagnosis of meningitis. Despite overlap in CSF findings from uninfected neonates and neonates with meningitis, most neonates have at least one abnormal finding on the initial CSF examination.

TABLE 39–20 Cerebrospinal Fluid Indexes in High-Risk Neonates without Meningitis

	Term	Preterm*
White Blood Cells (cells/mm^3)		
Mean	8.2	9.0
Range	0-32	0-29
Percentage PMNs	61.3	57.2
Protein (mg/dL)		
Mean	90	115
Range	20-170	65-150
Glucose (mg/dL)		
Mean	52	50
Range	34-119	24-63
CSF-to-Blood Glucose Ratio (%)		
Mean	81	74
Range	44-248	55-105

*Preterm infant defined as 28 to 38 weeks' gestational age.
CSF, cerebrospinal fluid; PMNs, polymorphonuclear neutrophils.
Adapted from Sarff LD et al: Cerebrospinal fluid evaluation in neonates: comparison of high-risk infants with and without meningitis, *J Pediatr* 88:473, 1976.

Other tests can be helpful in supporting or establishing a diagnosis of neonatal meningitis. The Gram-stained smear is the most useful. Antigen detection should not be used as a substitute for bacteriologic culture in the diagnosis of GBS meningitis. Results of antigen detection assays should be confirmed by culture.

Indications for obtaining CSF in the evaluation of infection are controversial. Some investigators have questioned the usefulness of lumbar puncture in the evaluation of asymptomatic newborns with maternal risk factors. In a retrospective study of 284 asymptomatic infants younger than 7 days of age with a sepsis workup that included lumbar puncture performed in response to maternal risk factors, Fielkow and associates[19] found no episodes of meningitis. Many authorities maintain that CSF should be obtained in any neonate with suspected sepsis neonatorum before antibiotics are given. Relying on a positive blood culture to determine when to evaluate CSF can miss 10% to 15% of neonates with meningitis and sterile blood cultures. The diagnosis of meningitis would have been missed or delayed in 16 of the 43 infants

TABLE 39–21 Cerebrospinal Fluid Values in Infants with Very Low Birthweight* by Postconceptional Age†

Postconceptional Age in Weeks (No. Infants)	Leukocytes/mm^3 ± SD (Range)	PMN (%) ± SD (Range)	Glucose (mg/dL) ± SD (Range)	Protein (mg/dL) ± SD (Range)
26-28 (17)	6 ± 10 (0-44)	6 ± 13 (0-50)	85 ± 39‡ (41-217)	177 ± 60‡ (108-370)
29-31 (23)	5 ± 4 (0-14)	10 ± 19 (0-66)	54 ± 18 (33-94)	144 ± 40 (84-227)
32-34 (18)	4 ± 3 (1-11)	4 ± 11 (0-36)	55 ± 21 (29-109)	142 ± 49 (54-260)
35-37 (8)	6 ± 7 (2-22)	5 ± 14 (0-40)	56 ± 21 (31-90)	109 ± 53 (45-187)
38-40 (5)	9 ± 9 (0-23)	16 ± 23 (0-48)	44 ± 10 (32-57)	117 ± 33 (67-148)

*<1500 g.

†Postconceptional age = gestational age + chronologic postnatal age.

‡Group at 26 to 28 weeks had significantly higher glucose and protein levels than the other groups ($P < .04$).

PMN, polymorphonuclear neutrophil; SD, standard deviation.

Data from Rodriguez AF et al: Cerebrospinal fluid values in the very low birth weight infant, *J Pediatr* 116:971, 1990.

reported by Wiswell and associates[73] if lumbar puncture had been omitted as part of the early neonatal sepsis evaluation. In a multicenter study of infants with VLBW, one third of 134 infants with late-onset meningitis had negative blood cultures.[66] Compared with noninfected infants, infants with meningitis had extended requirement for mechanical ventilation and hospitalization, and were more likely to have seizures and to die.

These data support the need to include a lumbar puncture in the diagnostic evaluation of infants with VLBW with suspected late-onset infection. Lumbar puncture can be delayed until a critically ill infant's status has stabilized or until correction of a coagulopathy, but omitting lumbar puncture as part of the evaluation would cause the diagnosis of meningitis to be delayed or missed completely in some infants.

TREATMENT

When initiating antimicrobial therapy for neonatal meningitis, potential pathogens and their susceptibility patterns and the achievable concentrations of the drugs in CSF should be considered. In the United States, empirical therapy should provide coverage for GBS, gram-negative bacillary enteric organisms, and *L. monocytogenes*. Ampicillin reliably provides coverage for GBS and *Listeria* organisms, but its activity against gram-negative enteric organisms is variable. When used for meningitis, ampicillin must be given in a higher dosage than that used for infections outside the nervous system to achieve adequate CSF concentrations. Although gentamicin is active against most gram-negative enteric organisms, aminoglycosides in general do not achieve satisfactory activity in CSF and are rarely used as monotherapy for treatment of meningitis.

When gram-negative bacillary meningitis is suspected, many clinicians favor using ampicillin, gentamicin, and cefotaxime pending final culture and susceptibility reports. Therapy for hospitalized neonates with late-onset meningitis should include coverage against nosocomial pathogens. Vancomycin and an aminoglycoside are frequently chosen to provide activity against CONS in addition to GBS and enterococci. If GBS is suspected, ampicillin should be included in the regimen. If enteric gram-negative organisms are suspected, cefotaxime should be added to the regimen. Antimicrobial therapy often can be simplified when the etiologic agent and its susceptibility profile have been determined.

The duration of therapy for culture-proven bacterial meningitis depends on the etiologic agent recovered and the infant's clinical response. The minimal duration in uncomplicated GBS or *Listeria* meningitis is 14 days. Gram-negative bacillary organisms are more difficult to eradicate from CSF. These infants often have persistently positive CSF cultures 3 to 4 days after the initiation of appropriate antimicrobial agents. In an uncomplicated case, the duration of therapy should be a minimum of 3 weeks, or 2 weeks after documented sterilization of CSF, whichever is longer. Examination of CSF, Gram-stained smears, and culture should be repeated routinely at 24 to 48 hours after initiation of therapy to document CSF sterilization and again near completion of therapy to document adequacy of treatment.

Supportive care of a newborn with meningitis is similar to that described for sepsis. In addition, treatment of seizures and inappropriate secretion of antidiuretic hormone may be necessary (see Chapter 40, Part 5). Neuroimaging is useful to assess ventricular size and to assist in delineating potential intracranial complications of meningitis.

PROGNOSIS AND OUTCOME

The mortality rate of neonatal meningitis has declined from almost 50% in the 1970s to contemporary rates of less than 10%. Survivors are at a high risk for neurologic sequelae.[26] A poor early outcome after GBS meningitis correlates with coma or semicoma, need for pressor support, total peripheral leukocyte count less than 5000/mm^3, absolute neutrophil count less than 1000/mm^3, and CSF protein greater than 300 mg/dL at the time of presentation.[33] Seizures at presentation, the burden of bacteria observed on Gram stain, and the severity of hypoglycorrhachia on the initial CSF sample are not predictive of sequelae at hospital discharge. Factors associated with poor outcome in gram-negative bacillary meningitis include CSF protein level greater than 500 mg/dL, CSF leukocyte count greater than 10,000/mm^3, persistence of positive CSF cultures, and presence and persistence of elevated IL-1α and TNF.[39] For *E. coli* meningitis, the presence and persistence of K_1 capsular polysaccharide antigen and the concentration of endotoxin in the CSF correlated with poor outcome. One fourth to one third of the survivors of gram-negative and gram-positive neonatal meningitis experience permanent sequelae resulting in significant neurologic damage, including hearing loss, language disorders, mental retardation, motor impairment, seizures, and hydrocephalus.[63] Clinical follow-up and neurodevelopmental assessment are appropriate after this disease.

Meningoencephalitis

Infection of the brain and meninges caused by viruses, fungi, or protozoal parasites can occur in the neonatal period. Transplacental infection with CMV, rubella virus, and *Toxoplasma gondii* and perinatal infection with HSV are discussed in other parts of this chapter. Poliovirus, coxsackievirus, echoviruses, varicella-zoster virus, and Epstein-Barr virus can be acquired before, at, or after delivery. Disorders caused by these agents, tuberculosis, and syphilis are discussed in greater detail later. When conventional bacterial cultures of CSF are sterile in an infant with clinical evidence of CNS infection or evidence of inflammation on examination of CSF, or both, these agents and *Mycoplasma hominis* should be considered. In young infants, it is usually impossible to distinguish clinically between meningitis, meningoencephalitis, and encephalitis. Identification of the etiologic agent and specialized radiologic studies can be helpful in this regard.

Pneumonia

INCIDENCE

Pneumonia is the most common form of neonatal infection and one of the most important causes of perinatal death worldwide.[42] (See also Chapter 44.) In the 1920s and 1930s, pneumonia was found at autopsy in 20% to 30% of stillborn and newborn infants. More recently, intrauterine pneumonia has been reported in 5% to 35% of autopsies.

ETIOLOGY

Neonatal pneumonia is caused by many of the same pathogens associated with neonatal sepsis. When the disease is acquired in utero or at the time of delivery, GBS is a common bacterial pathogen, although infections with *E. coli,* other gram-negative enteric organisms, *Listeria* species, *H. influenzae, T. pallidum,* staphylococci, and *S. pneumoniae* have been described. Other causative agents include *Chlamydia trachomatis, Mycoplasma pneumoniae,* CMV, HSV, enterovirus, adenovirus, and rubella. When disease is acquired in the nursery or at home, the same organisms can be responsible, but infection with *S. aureus, Pseudomonas, Serratia, Bordetella pertussis,* and *Candida* species should be considered, especially in premature infants with VLBW who receive care in intensive care units. Viral pneumonia can be noted at or shortly after birth, and reports of epidemic disease in the nursery have occurred with respiratory syncytial virus, echovirus, and adenovirus. Epidemic bacterial pneumonia has occurred after contamination of respiratory equipment and from personnel with suppurative staphylococcal lesions.

PATHOGENESIS AND PATHOLOGY

Pneumonia can be acquired (1) transplacentally, (2) by aspiration of contaminated amniotic fluid before or at the time of delivery, (3) by aspiration of infected materials during or after delivery, (4) by inhalation of aerosols from infected personnel or contaminated equipment in the newborn nursery, or (5) hematogenously during the course of septicemia or from another focus of infection. Congenital (intrauterine) pneumonia frequently follows prolonged ROM. Gasping from asphyxia can result in the aspiration of infected amniotic fluid. Pathologic findings of congenital pneumonia reveal a diffuse inflammatory process with neutrophils present in the alveoli, but bacteria often absent. Amniotic debris and maternal leukocytes can be found, suggesting that disease has followed aspiration rather than hematogenous dissemination of microorganisms. Features commonly observed in bacterial pneumonia in older patients are not seen, such as infiltration of bronchopulmonary tissue, fibrinous alveolar exudate, and pleural reaction.

Aspiration during or after delivery can result in bronchopneumonia, which is sometimes associated with hemorrhage and with evidence of pleural inflammation. Pathologic studies reveal areas of densely cellular exudate with bacteria present. Vascular congestion, hemorrhage, and necrosis can be observed. Microabscesses and empyema can be found when the infection is caused by *S. aureus* or *Klebsiella pneumoniae*. Pneumatocele formation, commonly associated with infection by *S. aureus,* has been described in neonatal disease caused by *E. coli* and *Klebsiella* species. Fatal cases of GBS pneumonia have had evidence of hyaline membranes similar to those found in respiratory distress syndrome.

CLINICAL MANIFESTATIONS

Pneumonia should be suspected when respiratory distress develops in any infant, but suspicion should be heightened if antecedent problems referable to pregnancy and delivery have been noted. Infants with congenital pneumonia often die in utero or are critically ill at birth. Spontaneous respirations may not occur or may be established with difficulty. If respirations are established, tachypnea, moderate retractions, and grunting may be observed. Fever may or may not be noted, but is often a prominent sign of neonatal herpes simplex and enteroviral disease. In most cases, there is no cough. Cyanosis can be constant or intermittent, and respirations may be irregular and punctuated by periods of apnea. Congestive heart failure, manifested by cardiac enlargement, hepatomegaly, and tachycardia, can complicate the pneumonic process.

Infants who acquire pneumonia during delivery or postnatally can have systemic signs, including fever, reluctance to feed, and lethargy. Respiratory signs can occur early or late in the course and include cough, grunting, costal and sternal retractions, flaring of the alae nasi, tachypnea or irregular respirations, rales, decreased breath sounds, and cyanosis. Congestive heart failure can be present in severe disease.

Postnatally acquired pneumonia can develop at any age. Infants with chlamydial pneumonia typically present at 4 to 11 weeks of age with a prodrome of nasal congestion followed by tachypnea and a paroxysmal, staccato cough. Conjunctivitis is present or occurred earlier in approximately half of these infants. Inspiratory rales may be present, but expiratory wheezes are not commonly seen. These infants are afebrile and frequently gain weight slowly.

DIAGNOSIS

Chest radiographs are necessary to support the diagnosis of pneumonia and to exclude other causes of respiratory distress. In some patients, no abnormality is found if imaging is performed soon after the onset of symptoms, but by 24 to 74 hours, a diagnosis should be possible. Radiographic findings can reveal bilateral homogeneous consolidation when pneumonia is acquired in utero or diffuse bronchopneumonia with postnatally acquired disease. Pneumatoceles can be observed, usually later in the course of illness, and occasionally hemothorax or pleural effusions are seen. Pneumonia caused by GBS can be difficult to distinguish radiographically from respiratory distress syndrome. This can be a diagnostic dilemma, especially in premature infants. Bilateral, symmetric interstitial infiltrates with hyperexpansion of the lungs are the typical radiographic findings seen in *C. trachomatis* pneumonia (see Chapter 37).

The radiographic pattern of segmental or lobar atelectasis can be difficult to distinguish from that of massive meconium aspiration. In meconium aspiration, opacities may be distributed in the same manner as in bronchopneumonia, but the radiologic changes tend to be maximal early and disappear rapidly during the ensuing days. In contrast, the patchy opacifications noted with bronchopneumonia tend to be minimal early and become more impressive during the subsequent days.

Blood cultures should be obtained in infants with pneumonia; positive cultures establish an etiologic diagnosis. If obtained before 8 hours of age, Gram-stained smears of tracheal secretions showing neutrophils and bacteria can help identify neonates with pneumonia. Bacterial cultures of tracheal secretions may not be helpful in establishing an etiologic diagnosis because they often reflect the flora present in the vaginal canal. In newborns with prolonged ventilation, tracheal aspirate cultures frequently fail to identify the cause of respiratory deterioration.[70] A definitive microbiologic diagnosis can be made if organisms are isolated from cultures of pleural fluid, material aspirated from lung abscesses, or open lung biopsy tissue, but these interventions often are not performed. Tracheal secretions should be processed for viral isolates when nonbacterial pneumonia is suspected.

A diagnosis of *Chlamydia* pneumonia can be assumed if the organism is isolated from nasopharyngeal samples or from secretions obtained by deep tracheal suctioning, but special culturing techniques are required. Culture of *B. pertussis* requires inoculation of nasopharyngeal secretions onto appropriate media for isolation. Cultures tend to grow slowly. Polymerase chain reaction of nasopharyngeal or endotracheal secretions provides a rapid and preferable means for diagnosis of pertussis.

TREATMENT

When a diagnosis of pneumonia is suspected, antimicrobial therapy should be initiated promptly. If the diagnosis is supported by historical and clinical findings, but initial radiographs fail to confirm the clinical suspicion, treatment should not be delayed and is continued until results of a repeat chest radiograph, taken at 48 to 72 hours, are available. Empirical antimicrobial therapy is the same as that for neonatal sepsis. Ampicillin and either an aminoglycoside or cefotaxime are indicated for early-onset or late-onset, community-acquired pneumonia, and vancomycin and an aminoglycoside are indicated for late-onset nosocomial infection (see Tables 39-17 and 39-18).[41] Pneumonia caused by *Chlamydia* or *Pertussis* organisms responds best to treatment with azithromycin. Acyclovir therapy should be administered promptly if HSV pneumonia is suspected. Treatment for bacterial pneumonia is continued for 10 to 14 days or longer as dictated by the clinical course of the patient. Adequate fluids and oxygen, as required to treat hypoxemia, are useful adjunctive measures.

PROGNOSIS

The outcome of intrauterine pneumonia is variable, but more critically ill infants are likely to die in utero or within the first 2 days of life despite meticulous care and administration of appropriate antibiotics. The prognosis is worse for premature than for term infants. In the absence of other problems, the prognosis for term infants who acquire pneumonia postnatally seems to be good.

Otitis Media

INCIDENCE

Acute otitis media is the most common infection diagnosed in young children, and it can occur in neonates. In one prospective study, 9% of infants had an episode of otitis media by age 3 months.[68] The exact incidence is uncertain. It is estimated that otitis media develops in a minimum of 0.6% of all live births during the first month of life, and that the rate may reach 2% to 3% in premature infants. Otitis media occurs more often in male than in female infants, in infants with cleft palate, and in infants requiring prolonged intubation.

ETIOLOGY

The microbiology of acute otitis media in neonates differs from acute otitis media seen in older infants and children. Although organisms from the respiratory tract are also the most commonly isolated pathogens in neonatal disease, GBS, *E. coli,* and other gram-negative bacteria can be causative agents in the first 2 to 6 weeks of life. Studies of infants younger than 6 to 8 weeks have shown that *S. pneumoniae* was the pathogen isolated in 19% to 30% of cases, *H. influenzae* was recovered in 14% to 25% of cases, and β-hemolytic streptococci (groups A and B) were recovered in 5% of cases. Gram-negative bacilli (*E. coli* and *Enterobacter, Klebsiella,* and *Pseudomonas* species) were found in 7% to 18% of neonates or very young infants with otitis media.[6,57] Of cultures obtained by tympanocentesis in this age group, 40% to 50% have been sterile or judged nonpathogenic. Included among the nonpathogenic bacteria are organisms such as *S. aureus, Staphylococcus epidermidis,* and *Moraxella catarrhalis,* which likely are responsible for purulent otitis media in some newborns. Because strict anaerobic culture techniques were not used in most studies, many sterile isolates may have contained anaerobic microorganisms. Viral infection also has been associated with neonatal middle ear disease.

PATHOGENESIS AND PATHOLOGY

Otitis media is more common in premature than in term infants. This increased risk of infection may be related to the small size of the eustachian tube, with resultant obstruction and secondary infection. Aspiration of infected amniotic fluid is probably a leading cause of otitis media in newborns. The disease increases in frequency in bottle-fed infants, a finding that may be related to use of the supine position during feeding or to the lack of local immunity that may be conferred by ingredients in breast milk. Secretory IgA and other components in breast milk may exert protection by preventing the attachment of otitis media–causing bacterial strains to retropharyngeal or buccal epithelial cells.

CLINICAL MANIFESTATIONS

The most common presenting symptoms are respiratory complaints such as cough or rhinorrhea and fever.[6] Irritability, lethargy, vomiting, poor feeding, or diarrhea can also be present. Young infants with otitis media often are asymptomatic. The ear is difficult to examine adequately in newborn infants. Erythema, dullness, and bulging of the pars flaccida of the tympanic membranes can be noted, and pneumatic otoscopy can reveal decreased mobility of the tympanic membrane. Infants with typical facial or submandibular GBS cellulitis often have ipsilateral otitis media.

DIAGNOSIS

The nonspecificity of clinical signs and symptoms combined with difficulties in visualizing the tympanic membrane early in life probably account in part for the discrepancy between incidence data derived from prospective clinical studies and data from postmortem studies. In infants who appear ill or fail to respond to initial therapy, a specific diagnosis should be made by culture and Gram-stained smears of purulent middle ear fluid obtained by myringotomy or tympanocentesis. Cultures of the nasopharynx can yield the same organism in some cases, but cannot be routinely relied on to guide selection of antibiotics. Blood cultures can be helpful in patients with concomitant septicemia. Lumbar puncture should be performed to exclude meningitis in ill infants. Meningitis that was not suspected before examination of CSF has been noted in some newborns with otitis media, but the frequency with which the two occur simultaneously is unknown.

TREATMENT

The empirical antibiotics chosen and the route administered depend on the age and the appearance of the infant. For neonates with acute otitis media in the first 2 weeks of life, a combination of ampicillin and either an aminoglycoside or cefotaxime provides effective initial treatment. Hospitalized premature infants require parenteral therapy as well. A regimen such as vancomycin and gentamicin is one option for empirical therapy. Oral therapy with amoxicillin can be considered for well-appearing term infants older than 3 weeks who have had an uncomplicated intrapartum and neonatal course. If the infant is toxic-appearing or has evidence of infection elsewhere, cultures of middle ear fluid, blood, and CSF should be obtained, and the infant should be hospitalized for broad-spectrum parenteral antimicrobial therapy. When culture results are known, antibiotic therapy can be altered appropriately. Treatment should be continued for 10 days or longer, depending on the etiologic agent, the associated condition (e.g., sepsis or meningitis), and the clinical response to therapy.

PROGNOSIS

Recurrent or persistent disease can occur. Infants with onset of otitis media before 2 months of age are at high risk for development of chronic otitis media with effusion. In addition to young age at the onset of the first episode, other risk factors for recurrent infections include low socioeconomic status and the presence of smokers in the household. Careful follow-up evaluation for infection and hearing loss is important. Insertion of tympanostomy tubes may be indicated to ensure adequate drainage of the middle ear and to reduce the likelihood of recurrent middle ear infections.

Conjunctivitis

INCIDENCE

Neonatal conjunctivitis, also referred to as ophthalmia neonatorum, is the most common ocular disease in neonates.[23] Previously, gonococcal conjunctivitis was the leading cause of infant blindness. The epidemiology of ophthalmia neonatorum in the United States has changed significantly, however, in the past century with the introduction of ocular prophylaxis by Credé in 1881 and the advent of prenatal screening and treatment of maternal gonococcal infections. Gonococcal conjunctivitis remains an important neonatal disease in less developed countries. In developed countries, ophthalmia neonatorum can be caused by chemical irritation after prophylactic instillation of silver nitrate into the conjunctival sac. Chemical conjunctivitis can occur in 10% to 90% of infants so treated. Chemical conjunctivitis caused by topical therapy with erythromycin or tetracycline occurs less frequently. The incidence of other forms of conjunctivitis is difficult to assess, but has been estimated at approximately 8 cases of chlamydial infection per 1000 live births and 0.3 cases of gonococcal disease per 1000 live births.

ETIOLOGY

The differential diagnosis of infectious conjunctivitis in a newborn includes bacterial, chlamydial, and viral agents. *C. trachomatis* and *Neisseria gonorrhoeae* are the most important causes of conjunctivitis in the newborn period with respect to frequency of the former and severity of complications in untreated cases for both. Other bacteria, including *S. aureus,* GBS, *Pseudomonas* species, *S. pneumoniae,* and *Haemophilus* species, can also be causative. Conjunctivitis is the most common ocular manifestation of neonatal herpes simplex infections.

PATHOGENESIS

Conjunctivitis caused by *N. gonorrhoeae, C. trachomatis,* GBS, or HSV usually is initiated by infection with microorganisms acquired during passage through the birth canal and reflects the prevalence of sexually transmitted diseases in the community. Premature ROM and prematurity increase the risk of disease by *N. gonorrhoeae*. Infection with *S. aureus* or other organisms more commonly reflects infection acquired postnatally. *Pseudomonas* conjunctivitis occurs most often in hospitalized premature infants and often is associated with systemic complications.

CLINICAL MANIFESTATIONS

The typical age at onset of conjunctivitis varies depending on the etiology, although there is much overlap. Chemical conjunctivitis usually is noted soon after birth and becomes less prominent within 48 hours. Bacterial conjunctivitis is most prominent during the first week of life, but can occur at any time during the neonatal period. Chlamydial conjunctivitis usually develops during the second week of life.

The signs of bacterial conjunctivitis in a newborn are similar to the signs observed in older patients. A purulent ocular discharge, erythema and edema of the lids, and injection or suffusion of the conjunctiva can be found. Gonococcal disease typically manifests with abrupt onset of profuse, purulent ocular discharge. Conjunctivitis caused by *Haemophilus* species and *S. pneumoniae* has been associated with dacryocystitis. When *C. trachomatis* is involved, minimal inflammatory changes may be detected, or there can be intense inflammation, swelling, and a yellow discharge associated with pseudomembrane formation. The cornea is affected rarely. Chlamydial infections usually are bilateral, whereas unilateral disease is common when staphylococcal disease is present.

Complications are rare, but can be devastating, with loss of vision. If bacterial conjunctivitis is left untreated, corneal involvement with punctate epithelial erosions can occur. In the case of disease with *N. gonorrhoeae,* large, punctate, superficial lesions can be seen that can coalesce and progress to corneal perforation. Gonococcal conjunctivitis should be considered a medical emergency. Untreated disease can progress rapidly from purulent conjunctivitis without corneal involvement to corneal ulceration and perforation. Meningitis or arthritis can complicate gonococcal ophthalmia neonatorum, but systemic spread of infection occurs rarely when appropriate therapy is given promptly before corneal involvement develops. When staphylococcal conjunctivitis is complicated by corneal involvement, the lower portion of the cornea is infected more frequently than the upper half, and marginal corneal infiltrates with peripheral vascularization can be seen. When chlamydial conjunctivitis is not treated, inflammation persists for 1 or 2 weeks. A subacute phase follows with slight injection of the conjunctiva and an accumulation of purulent material along the lid margins. Necrosis of the cornea has been observed, followed by fibrosis and scarring of the lid margin. Occasionally, chronic disease develops. Untreated chlamydial conjunctivitis, especially when associated with nasopharyngeal colonization, can progress to pneumonia in some infants. Even without invasive eye disease, systemic complications such as bacteremia and meningitis often develop in infants with *P. aeruginosa* conjunctivitis.

DIAGNOSIS

A presumptive diagnosis of chemical or infectious conjunctivitis can be made based on the history and physical examination. There is such overlap in clinical appearance and age at presentation that a definitive etiologic diagnosis cannot be determined reliably without the aid of laboratory testing. Purulent material must be sent for Gram stain and bacterial culture. Conjunctival scrapings should be sent when evaluating for *Chlamydia* infection because the organism resides in the epithelial conjunctival cells and not in neutrophils.

When gonococcal disease is suspected, the purulent material should be placed in special transport media and sent to the bacteriology laboratory. Other organisms are less fastidious, and a swab of purulent material, cultured promptly, is sufficient to establish a diagnosis. The presence of intracellular gram-negative diplococci on a Gram-stained smear suggests a diagnosis of gonococcal disease.

Characteristic intracytoplasmic inclusions can be identified by examining a Giemsa-stained smear from material obtained by gently but firmly scraping the lower portion of the palpebral conjunctiva with a blunt spatula or loop. Care must be taken not to injure the conjunctiva during the process. Leber cells (macrophages containing cellular debris) and inclusion-bearing epithelial cells (hence the name inclusion blennorrhea or conjunctivitis) are characteristic. The Giemsa stain is a specific, but not a sensitive, method for detection of *Chlamydia* conjunctivitis. Culture is the gold standard, but many laboratories do not have the capability of performing cell cultures. Numerous antigen detection assays, such as nucleic acid amplification and direct fluorescent antibody tests, are also options with a high degree of accuracy for detection of *Chlamydia* from conjunctival specimens.

TREATMENT

Therapy of gonococcal conjunctivitis involves frequent irrigation of the conjunctival sac with sterile isotonic saline until the discharge has resolved and parenteral antimicrobial therapy. The recommended antimicrobial therapy for ophthalmia neonatorum is ceftriaxone (25 to 50 mg/kg, not to exceed 125 mg) administered intravenously or intramuscularly one time. Evaluation for disseminated infection should include cultures of blood and CSF. For disseminated neonatal gonococcal infection, the recommended therapy is ceftriaxone (25 to 50 mg/kg) given once daily for 7 days or cefotaxime (50 to 100 mg/kg daily) given in two doses for 7 days. If meningitis is documented, treatment should be continued for 10 to 14 days. Persistence of conjunctivitis after treatment may indicate coinfection with *C. trachomatis* and requires additional therapy directed against this agent. Because there are reports of high rates of *C. trachomatis* and *N. gonorrhoeae* coinfection in adults, empirical treatment with erythromycin in addition to cephalosporin often is indicated.

Parenteral treatment with an aminoglycoside and an antipseudomonal penicillin in addition to topical treatment is indicated for conjunctivitis caused by *Pseudomonas* organisms. Antibiotics containing various combinations of bacitracin, neomycin, and polymyxin, administered topically as an ophthalmic ointment or solution several times a day for 7 to 10 days, have been recommended for other forms of bacterial conjunctivitis.

An association between orally administered erythromycin and infantile hypertrophic pyloric stenosis has been reported in infants younger than 6 weeks. The efficacy of a single erythromycin course for treatment of *Chlamydia* conjunctivitis was approximately 80%. Preliminary data indicate that a short course of azithromycin treatment is an effective alternative to erythromycin,[25] and azithromycin now is the treatment of choice for infants with chlamydial conjunctivitis. Topical treatment is ineffective and is not indicated.

PREVENTION

The CDC and the American Academy of Pediatrics Committee on Infectious Diseases recommend erythromycin (0.5%) ophthalmic ointment, tetracycline (1%) ophthalmic ointment, or a 1% silver nitrate solution for prophylaxis of ophthalmia neonatorum. The prophylactic agent should be dispensed in a single-dose tube or ampule and given within 1 hour of birth.

In a large study by Hammerschlag and colleagues[24] in which the efficacy of three topical prophylactic agents was studied in 230 infants born to women diagnosed with cervical chlamydial infection during pregnancy, 20% of infants given silver nitrate at birth, 14% of infants given erythromycin, and 11% of infants given tetracycline topical prophylaxis developed neonatal chlamydial conjunctivitis. This observation and findings from several other studies suggest that the most effective way to prevent chlamydial conjunctivitis (and other chlamydial disease) in neonates is to screen and treat pregnant women harboring the infection. Infants born to mothers known to have untreated chlamydial infection are at high risk for infection; however, prophylactic antimicrobial treatment is not indicated because the efficacy is unknown.

Ceftriaxone, 25 to 50 mg/kg (maximum 125 mg), should be administered intravenously or intramuscularly as a single dose to infants born to mothers with untreated gonococcal infection. Cefotaxime, 100 mg/kg, is an alternative. Administration of one of the topical agents used for prophylaxis does not eradicate established gonococcal infection that is not yet clinically apparent. Caution should be exercised in providing ceftriaxone to premature infants of low birthweight with hyperbilirubinemia.

Gastroenteritis

INCIDENCE

Most neonatal diarrheal disease is sporadic. It is usually self-limited and brief, but may cause significant morbidity in some infants. Failure to take appropriate steps to control the spread of infection to other infants can result in an epidemic outbreak of the disease in the nursery. The incidence varies from nursery to nursery and within the same nursery from year to year.

ETIOLOGY

Neonatal diarrheal disease is more likely to be associated with noninfectious processes. The organisms that have been associated with epidemic and sporadic infectious diarrheal disease include certain strains of *E. coli; Salmonella, Shigella, Yersinia,* and *Campylobacter* species[49]; and rarely *Pseudomonas, Klebsiella,* and *Enterobacter* species and *Candida albicans*. An epidemic of enterocolitis has been attributed to infection by group A streptococci. Enteric types of adenovirus, rotavirus, and calicivirus have been identified as causative agents for gastroenteritis in neonates. In many cases, the etiologic agent is not identified, and viruses are assumed to be responsible despite negative viral and serologic studies.

There are at least five pathotypes of diarrhea-producing *E. coli*. Enteropathogenic *E. coli* (EPEC) was associated classically with severe outbreaks of infantile diarrhea in the developed world through the 1960s, and now is a common cause of diarrhea in infants in the developing world. There is a predilection for this infection in infants who are not breastfed. Enterotoxigenic *E. coli* also has been associated with neonatal diarrheal disease, but infection usually is delayed until the introduction of foods to supplement human milk.

All *Salmonella* organisms are closely related and are now considered a single species, *Salmonella enterica*. There are more than 2000 *Salmonella* types that cause human disease. Three surface antigens determine reactions to antisera: O (somatic), H (flagellar), and Vi (capsular) antigens. Serogrouping is based on O antigens and designates groups A through E. *Salmonella* serotype *typhi* is in group D. Commonly reported isolates in the United States include *Salmonella* serotype *typhimurium* (group B) and *Salmonella* serotype *enteritidis* (group D).

Shigella comprises four serogroups with more than 40 serotypes. In the United States, *Shigella sonnei* (group D) followed by *Shigella flexneri* (group B) are the most common isolates from patients of any age with shigellosis. The central event in pathogenesis for *Shigella* is its ability to cross the colonic epithelium and invade the colonic mucosa. All virulent *Shigella* organisms have virulent plasmid-associated antigens that provide the means for intracellular and intercellular spread. Hemolytic uremic syndrome, associated with production of Shiga toxin, can complicate bacillary dysentery secondary to *Shigella dysenteriae,* serotype 1.

Campylobacter, a comma-shaped, gram-negative bacillus, is recognized increasingly as a common cause of gastroenteritis. *Campylobacter fetus* causes prenatal and neonatal infections that result in abortion, premature delivery, bacteremia, and meningitis. *Campylobacter jejuni* and *Campylobacter coli* usually cause neonatal gastroenteritis. Health care–associated outbreaks in nurseries, although uncommon, have been described.

Although it is likely that some diarrheal episodes in neonates can be caused by *Clostridium difficile,* the diagnostic criteria used in older children and adults are inadequate to establish a definitive etiologic diagnosis in this age group. *C. difficile* is rarely isolated from the stools of healthy children older than 1 year or healthy adults, but the organism and its cytotoxin can be shown in the stools of more than 50% of healthy neonates. The pathogenicity of this organism in neonates has not been well defined.

PATHOGENESIS

The gastrointestinal tract is colonized initially by organisms that enter the oropharynx at delivery. Maternal carriers of *Salmonella, Shigella, Campylobacter,* and EPEC can serve as the initial source of these pathogens in the nursery. Person-to-person transmission also has occurred in neonates of infected mothers and has resulted in health care–related outbreaks in nurseries. Asymptomatic health care workers who are carriers of these organisms have proved to be the source of spread.

Fomite transmission has been observed, and in rare instances infection has followed ingestion of contaminated milk, water, or materials used for radiographic evaluation of the gastrointestinal tract.

CLINICAL MANIFESTATIONS

Gastrointestinal tract bacterial infection can manifest without clinical symptoms; as a watery diarrhea without other findings; or as a severe diarrhea with fever, vomiting, and abdominal distention. It is difficult to predict the etiology on the basis of clinical findings. Bloody diarrhea containing mucus suggests *Shigella, Yersinia,* or *Campylobacter* gastroenteritis, but these findings have been observed occasionally in neonates with gastroenteritis caused by *Salmonella* or EPEC. Infection with *Salmonella* is frequently asymptomatic or mild. Neonates with diarrhea usually have a self-limited infection with loose, mucoid stools and, rarely, hematochezia. *Salmonella* gastroenteritis in the first month of life can be associated with bacteremia or extraintestinal manifestations, including meningitis. Neonatal shigellosis is rare. The classic picture is that of dysentery, but asymptomatic infection occurs as well. Complications include hemolysis, hemolytic uremic syndrome, colonic perforation, and pseudomembranous colitis. Seizures associated with *Shigella* bowel infection are uncommon in the first 6 months of life. Sepsis occurs uncommonly, but the case-fatality rate is significant for infants with systemic infection.

Infections caused by *C. fetus* are the most common type of *Campylobacter* infection in the first 3 weeks of life and are associated with a high incidence of fetal and neonatal mortality. Systemic *C. jejuni* or *C. coli* infection in neonates is rare. A blue-green discoloration of the stools or diaper can be found when *Pseudomonas* species predominate. The isolation of *Pseudomonas* organisms does not represent disease. Dehydration, acidosis, electrolyte disturbances, and hypotension can occur during the course of disease caused by any of these enteric pathogens.

DIAGNOSIS

Stool for bacterial culture should be obtained from infants with gastroenteritis. Recovery of *Shigella, Yersinia, Campylobacter,* or *Salmonella* from the stool of an infant with diarrhea is presumptive evidence that disease is caused by that organism. The diagnosis of EPEC is difficult because most clinical laboratories cannot differentiate diarrhea-associated strains of *E. coli* from normal stool flora *E. coli* strains. Isolates of *E. coli* suspected to cause a case or outbreak should be sent to a state health or other reference laboratory for serotyping.

A stool smear for polymorphonuclear leukocytes can be valuable. Fecal leukocytes can be observed in stool smears from patients with diarrhea caused by EPEC, *Yersinia, Campylobacter, Salmonella,* or *Shigella,* but usually are not seen in patients with nonspecific or viral gastroenteritis. Blood cultures should be obtained from any neonate with isolation of *Salmonella, Shigella, Campylobacter,* or *Yersinia enterocolitica* from the stool. Lumbar puncture for examination and culture of CSF should be considered if the neonate is febrile or otherwise "toxic" in appearance, or if *Salmonella* or other potential pathogens are isolated from the blood culture.

TREATMENT

Supportive care and correction of fluid and electrolyte abnormalities are the most important aspects of management. Because many infections are self-limited, antimicrobial therapy may not be indicated except in certain situations. It may be unnecessary to treat an infant with diarrhea caused by EPEC. During nursery outbreaks, infants with EPEC isolated from stool should be treated independent of the symptoms, however. When antimicrobial therapy is given, nonabsorbable orally administered antibiotics (neomycin, colistin sulfate) are appropriate options, and the duration of treatment is 5 days.

Infants with *Salmonella* isolated from stool should be treated with cefotaxime after obtaining blood and CSF cultures. When bacteremia or meningitis is present, therapy with cefotaxime or ampicillin for susceptible strains should be given for 10 days (bacteremia) to 4 to 6 weeks (meningitis). Antimicrobial therapy is effective in shortening the duration of diarrhea caused by *Shigella* and eliminating organisms from the feces, and is recommended for patients with bacillary dysentery. For cases in which susceptibility is unknown, ceftriaxone or cefotaxime should be administered. For susceptible strains, ampicillin or trimethoprim-sulfamethoxazole are effective. Treatment should be administered for 5 days. *Campylobacter enteritis* may be treated with azithromycin. Benefit from antimicrobial therapy for patients with *Yersinia enterocolitis* has not been established. Patients with septicemia and compromised hosts, including premature infants, with enterocolitis should receive treatment, however. Cefotaxime and aminoglycosides are appropriate antimicrobials.

PREVENTION AND PROGNOSIS

In addition to standard precautions, contact precautions are indicated for infants with diarrhea. Clusters of infections should be investigated appropriately. During outbreaks of disease caused by EPEC, contact precautions should be maintained until tests of stools collected after completion of antimicrobial therapy are negative for the infecting strain.

Osteomyelitis and Septic Arthritis

INCIDENCE

Osteomyelitis occurs rarely in newborns and can be difficult to diagnose. Septic arthritis is frequently concomitant, probably reflecting spread of infection through blood vessels that penetrate the epiphyseal plate (see Chapter 54).

ETIOLOGY

The most frequent causative agents for community-acquired osteomyelitis and septic arthritis are *S. aureus, E. coli,* and GBS. Community-associated MRSA strains and health care–associated MRSA are common pathogens. Uncommon etiologic agents include *N. gonorrhoeae, H. influenzae,* group A streptococci, and *T. pallidum*. Various staphylococcal and streptococcal species and anaerobic bacteria have been cultured from scalp electrode–related cases of osteomyelitis. *Candida* species and gram-negative enteric bacilli have assumed major roles for nosocomially acquired bone and joint infections, especially in preterm infants with low birthweight. These infections are most commonly isolated in nursery outbreaks.

PATHOLOGY

Osteomyelitis usually originates in the metaphysis of long bones. Involvement of the small bones of the hands and feet, the vertebrae, and the ribs has been noted, however. Multiple foci of osteomyelitis are seen more frequently in newborns than in older individuals; 10% to 40% of newborns have more than a single focus of infection. The cortical bone is thin, permitting infection to extend readily into soft tissues. Infection extends readily from an affected bone into the adjacent joint via transphyseal vessels. Destruction of cartilage, dislocations, and pathologic fractures can occur and permanently affect bone growth.

PATHOGENESIS

Osteomyelitis almost invariably follows hematogenous dissemination of microorganisms. Infection of the skin, omphalitis, umbilical catheterization, and occasionally improperly performed femoral venipunctures are predisposing factors in cases principally caused by *S. aureus*. Occasionally, osteomyelitis can follow direct extension of a soft tissue infection to bone, especially if the underlying bone is fractured, as illustrated in cases of osteomyelitis of the skull associated with infected cephalhematomas. Transplacental acquisition with dissemination to bone has been observed with *T. pallidum*.

CLINICAL MANIFESTATIONS

Destructive changes in bone caused by osteomyelitis can be advanced by the time a definitive diagnosis is made. In some patients, the disease is not accompanied by systemic signs or symptoms. Fever is absent or is a very late, intermittent finding. Findings of swelling, tenderness, and decreased motion of an extremity usually prompt initial appraisal. In a patient with osteomyelitis of the clavicle, an incomplete Moro reflex can be the only finding on physical examination. Localized tenderness and erythema can be seen, and heat and fluctuance can be noted. Focal findings overlying affected sites occur commonly when *S. aureus* is the pathogen. Less often, infants have an acute onset of systemic illness with fever, icterus, hemorrhagic manifestations, and hypotension. GBS osteomyelitis commonly manifests during the third and fourth weeks of life. In contrast to the fulminant onset and poor outcome that occur in some patients with late-onset meningitis, GBS bone and joint infection often has an indolent nature and an almost uniformly good outcome.

DIAGNOSIS

When the history and physical examination suggest the possibility of osteomyelitis, imaging studies should be obtained. Plain radiographic bony changes are delayed for 7 to 10 days after onset of infection, but a plain radiograph provides a helpful baseline. The earliest finding is deep soft tissue swelling. Later in the course of infection, periosteal thickening, cortical destruction, irregularities of the epiphysis, and periosteal new bone formation are seen. Additional findings include localized areas of cortical rarefaction, periosteal elevation, a widened joint space, and subluxation or dislocation of the bone from the joint (e.g., the hip) (Fig. 39-10).

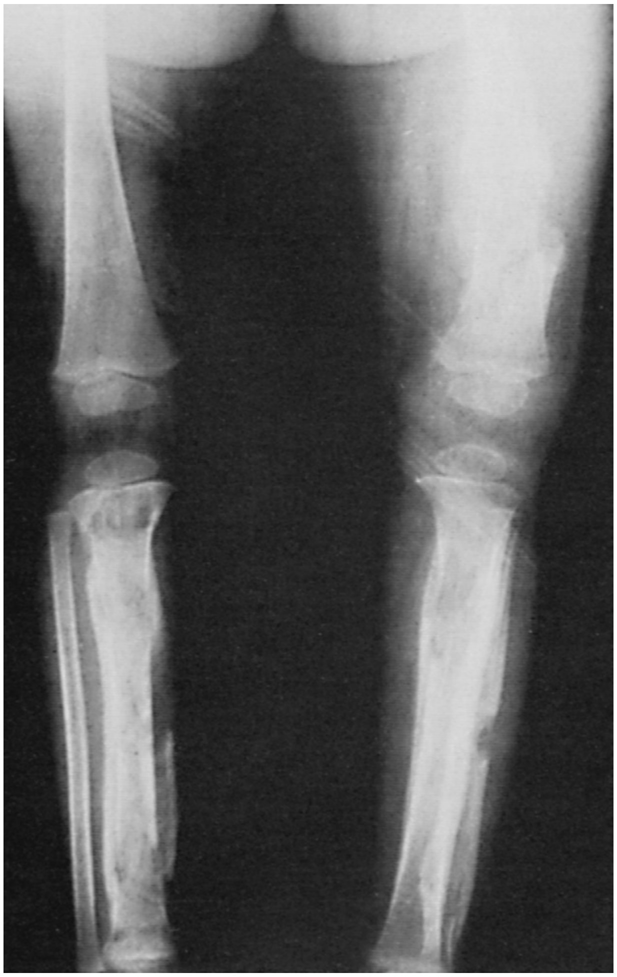

Figure 39–10. Radiographic evidence (posterior view) of multiple sites of osteomyelitis in an infant, the result of infection with *Staphylococcus aureus*. Clinical evidence of infection became apparent at 2 weeks of age. Osteolytic lesions can be seen in the right femur, right tibia and fibula, and left tibia. Periosteal new bone formation is visible in many areas.

Magnetic resonance imaging (MRI) is the diagnostic modality of choice for neonatal osteomyelitis. The diagnosis can be established within 24 to 48 hours after the onset of symptoms. The anatomic detail provided by MRI optimizes the definition of structural abnormalities and can guide surgical drainage. A technetium 99m phosphate scan can show areas of increased blood flow in the affected area, but this modality lacks the structural clarity of MRI and is rarely indicated.

Aspiration of soft tissues and bone is indicated, and samples should be sent for Gram stain and culture. Blood cultures are essential and have been reported to yield the causative agent in 60% of cases. Synovial fluid obtained from patients with joint involvement should be sent for Gram stain and culture. Because osteomyelitis frequently follows bacteremia, caregivers should consider obtaining CSF to exclude concomitant meningitis. Normal peripheral white blood cell counts are commonly seen in neonates with bone and joint infection, and ESR values less than 40 mm/h are reported in

25% of cases. Syphilis, tuberculosis, scurvy, rickets, and deep cellulitis must be considered in the differential diagnosis.

TREATMENT

Until the specific etiology has been clarified by culture, combination therapy should be initiated with vancomycin and either an aminoglycoside or an extended-spectrum cephalosporin for gram-negative coverage. When the infecting isolate and its susceptibility pattern have been identified, treatment should be continued with the most appropriate antibiotic. The dosages used should be the same as the dosages used for treatment of septicemia (see Tables 39-17 and 39-18). Parenteral therapy should be continued for 3 to 4 weeks or longer until clinical and radiographic findings indicate healing, and CRP and ESR are normal. Intra-articular administration of antibiotics is not indicated. Surgical drainage of purulent material is a key component of treatment, and consultation should be sought with a pediatric orthopedic surgeon in the management of this infection. When the hip or shoulder joints are involved, prompt surgical decompression and drainage are crucial.

PROGNOSIS

The degree of residual damage depends on the extent of disease before effective treatment. Permanent disability is more common when joint involvement has occurred. Growth disturbances can result from destruction of the epiphyseal plate. The number of foci of osteomyelitis in a patient who is effectively treated does not seem to correlate specifically with the extent or likelihood of permanent disability. Chronic osteomyelitis occurs infrequently. Overall, residual effects can be noted in 25% of neonates with infection of the bones and joints.

Urinary Tract Infection

The incidence of neonatal urinary tract infection varies from 0.1% to 1% of all infants, with a higher frequency in neonates with low birthweight. (See also Chapter 51.) In contrast to bacteriuria in all other age groups, neonatal disease is more commonly seen in male infants. This preponderance of male infants may reflect the increased risk of urinary tract infection in uncircumcised boys.[72] The presence of virulence factors in some bacteria also influences the development of urinary tract infections.

The organisms associated with neonatal urinary tract infection mirror those that cause neonatal sepsis. For community-acquired neonatal disease, infection with *E. coli* is most common. Although GBS can be isolated from the urine of infants with GBS sepsis, primary urinary tract infection is rare. The frequency of health care–associated urinary tract infection has increased with the survival of infants with VLBW. Pathogens causing health care–associated infections include *E. coli,* other gram-negative enteric bacilli, *Enterococcus, Candida,* and CONS.

Symptoms referable to the genitourinary system are rare. In most infants, the symptoms are nonspecific, similar to that of neonates with septicemia. Reluctance to feed, weight loss, and diarrhea can be the presenting features in some patients. An unexplained fever should prompt an investigation of the urinary tract in addition to an evaluation for sepsis and meningitis.

Urine culture need not be performed routinely in evaluation of infants with early-onset infection because isolation of a pathogen from the urine usually is a manifestation of sepsis, rather than an indicator of urinary tract infection. Definitive diagnosis of neonatal urinary tract infection for an infant evaluated beyond the first few days of life can be made only with culture of properly obtained urine. Samples collected by voiding into a bag are inappropriate. Catheterized specimens or samples obtained by suprapubic bladder aspiration are suitable. Isolation of any bacteria from a bladder aspirate is considered significant, whereas counts of 10^3 or higher colony-forming units per milliliter of catheterized urine are meaningful. Blood and CSF should be obtained as described in the evaluation for sepsis. Although the presence or absence of pyuria on examination of urine sediment is not conclusive evidence for diagnosing or excluding urinary tract infection, the presence of bacteria on Gram-stained smears of the sediment does support the diagnosis.

Empirical therapy for neonatal urinary tract infection should include ampicillin and an aminoglycoside in dosages used for sepsis. Administration should be parenteral because of the high incidence of sepsis in association with urinary tract infections in newborns, and because of the often erratic oral antibiotic absorption in infants. Vancomycin and an aminoglycoside should be considered for empirical therapy of health care–associated urinary tract infections.

Sterilization of the urine should be documented by repeat culture after 48 hours of therapy. Treatment duration is usually 10 days, but can be longer if there is persistent bacteriuria, anatomic obstruction, or a perinephric abscess. In uncomplicated cases of primary urinary tract infection, parenteral therapy can be given for 5 to 7 days, followed by oral antibiotic therapy to complete the course of treatment. Imaging studies, including renal ultrasound and voiding cystourethrogram or renal scan, should be performed to diagnose any anatomic or physiologic urinary tract anomalies.

Infections of the Skin

INCIDENCE

Infection of the skin is common and can be a result of bacterial, viral, or fungal disease. (See also Chapter 52.) The lesions may be localized or the cutaneous manifestation of systemic disease.

ETIOLOGY

Colonization of the skin begins at birth, and the organisms that initially are acquired reflect those present in the mother's birth canal. Subsequently, infants can acquire organisms from the environment or from the hands of family members or caregivers. *S. aureus* is the organism most often associated with neonatal skin infections. Application of triple dye, iodophor ointment, or chlorhexidine powder to the umbilical stump has been used to delay or prevent *S. aureus* colonization. Virtually any organism that causes disease in infancy can result in cutaneous infection, including group A streptococci and GBS, *Listeria, P. aeruginosa, T. pallidum,* HSV, and *C. albicans*.

PATHOLOGY

Histologic examination of the skin of patients with bullous impetigo can show intraepidermal bullae filled with polymorphonuclear leukocytes. Ritter disease, a severe generalized form of staphylococcal scalded skin syndrome, is caused by a toxin-elaborating strain of *S. aureus*. It is characterized by a severe bullous eruption with shedding of the epidermis. Histologic examination of the skin reveals an intraepidermal blister, cellular death and acantholysis, and a striking absence of inflammation. *Pseudomonas* or *Aeromonas hydrophila* infections cause ecthyma gangrenosum, which is characterized by the development of yellow-green pustules that progress rapidly to form hemorrhagic and necrotic ulcers. In most neonates with ecthyma gangrenosum, these lesions have developed as a consequence of bacteremia. Skin abscesses with minimal inflammation may be caused by *Candida* species; their occurrence should be considered diagnostic of invasive infection.[3]

PATHOGENESIS

Infection usually develops as a result of a small break in the skin and is caused by organisms that have colonized the skin and nares. Potential risk factors include abrasions after forceps use, scalp wounds associated with intrapartum fetal monitoring, the process of degeneration of the umbilical stump after cord clamping, intravascular catheter use, and circumcision. Infectious complications after severing the umbilical cord or circumcision were common before aseptic surgical techniques were introduced.

CLINICAL MANIFESTATIONS

Skin and soft tissue infections should be discovered promptly because clinical findings usually are apparent on casual observation. Lesions include pustules, vesicles, bullae, maculopapules, cellulitis, impetigo, abscesses, petechiae, purpura, and erythema multiforme.

The most frequently observed lesion is a maculopapular rash that is nonspecific and can be seen with bacterial infections (staphylococcal and streptococcal), fungal infections, and viral infections (measles, enteroviruses, rubella). Bullous lesions that appear after the second day of life usually suggest staphylococcal disease, in contrast to noninfectious blistering disease that is present at birth. Blisters can range in size from small vesicles to larger bullae filled with straw-colored fluid. When these lesions rupture, an erythematous, weeping, denuded area is present. In staphylococcal scalded skin syndrome, the epidermis can be shed in sheets, and intact bullae frequently are sterile. HSV, *T. pallidum, P. aeruginosa,* and GBS less frequently are associated with bullous lesions.

Pustules are a common manifestation of staphylococcal disease, but can be seen with listeriosis as well. Impetigo and erysipelas should suggest streptococcal infection. Less commonly, impetigo can be caused by *S. aureus* or *E. coli*. GBS has been associated with the triad of cellulitis, adenitis, and bacteremia. Cellulitis and soft tissue abscesses are the hallmark of infection with *S. aureus,* but occasionally can be caused by streptococci or *E. coli*. Erythema multiforme can occur during neonatal sepsis with *S. aureus,* streptococci, or *Pseudomonas.*

Congenital syphilis may be suggested by the presence of maculopapular lesions, and in some cases bullae have been noted at birth, particularly on the palms and soles. The blisters develop on an erythematous base and may consist of cloudy or hemorrhagic fluid that contains spirochetes. When the blisters rupture, a macerated area remains on which crusts form. A diagnosis of *Pseudomonas* or *Aeromonas* infection should be suspected in patients with ecthyma gangrenosum.

Candida infection may be localized to the oral cavity or the diaper area, or both. Early cutaneous lesions are vesicular with a surrounding area of erythema. Pustules may develop, and a confluent erythematous moist erosion is soon noted. Cutaneous manifestations of congenital candidiasis characteristically are present at birth or within hours of delivery. A diffuse, burnlike dermatitis has been described in several infants with low birthweight (<1500 g) as an early manifestation of systemic candidiasis.

In the early stages of infection with *S. aureus, Listeria,* GBS, or *Pseudomonas,* vesicles may be present. Herpes simplex and varicella zoster viruses produce vesicular lesions that are similar in appearance clinically and histologically.

DIFFERENTIAL DIAGNOSIS

Noninfectious processes that can be mistaken for the cutaneous manifestation of infection include milia, transient pustular melanosis, erythema toxicum, and sclerema neonatorum. (See Chapter 52.) Purpuric and bullous lesions can result from trauma, inherited skin disorders such as epidermolysis bullosa, acrodermatitis enteropathica, dermatitis herpetiformis, and mastocytosis. Coagulopathies and congenital leukemia can be associated with purpura.

DIAGNOSIS

A diagnosis should be based on stains and bacterial, fungal, and viral cultures of the lesion. In patients with staphylococcal scalded skin syndrome, microorganisms may not be present in the intact bullous lesions. *Candida* can be shown by use of a potassium hydroxide preparation that shows pseudohyphae. Skin biopsy may be required to document the depth of invasiveness. Dark-field examination of bullous lesions usually reveals *T. pallidum* in an infant with congenital syphilis. When this diagnosis is suspected, appropriate serologic studies must be performed, and contact precautions must be undertaken. Fluid obtained by aspiration of vesicles may permit identification of disease caused by various viral agents. Blood cultures should be obtained and may be positive in neonates with systemic infection or with staphylococcal or streptococcal disease.

TREATMENT

When lesions are localized and superficial, local therapy can suffice for neonatal staphylococcal pustulosis in an otherwise healthy term infant. Other manifestations of staphylococcal infections and most other bacterial infections of the skin should be treated by parenteral administration of antibiotics. Nafcillin is appropriate for methicillin-susceptible strains of staphylococci, and vancomycin should be used for MRSA. Streptococcal infections can be treated with penicillin G, ampicillin, or a third-generation cephalosporin. An aminoglycoside, an extended-spectrum penicillin, or ceftazidime should provide coverage for ecthyma gangrenosum caused by *P. aeruginosa*. Treatment of cutaneous fungal infections is discussed in Part 3 of this chapter.

Parenteral fluid therapy may be required to maintain hydration in patients with staphylococcal scalded skin syndrome. Specific attention should be paid to maintenance of adequate hemoglobin and serum albumin concentrations and of the body temperature. Incision and drainage are required if abscesses are found.

Full evaluation for disseminated disease should be carried out, and treatment should be initiated promptly with acyclovir for vesicular lesions presumed to be caused by HSV. Early initiation of treatment may prevent dissemination of localized infection and optimize outcome of generalized herpes infection heralded by cutaneous lesions. (See also Part 4.)

Omphalitis

INCIDENCE

Omphalitis was previously an important cause of neonatal disease and death worldwide. Since the introduction of simple umbilical cord hygienic measures, it is rarely seen in developed countries, but it remains an important cause of neonatal illness elsewhere. The incidence is unknown. Umbilical phlebitis and arteritis may develop spontaneously or may follow catheterization of umbilical vessels. Tetanus may follow contamination of the umbilical stump, but is rarely encountered in societies that practice routine immunization for tetanus and asepsis at the time of delivery. Necrotizing fasciitis is a life-threatening complication resulting from rapidly spreading destruction of the fascia and subcutaneous tissue around the umbilicus.

ETIOLOGY

Organisms that are found on the skin or that are introduced into the umbilical vessel by catheterization can produce omphalitis. *S. aureus* and *E. coli* are frequent pathogens, but group A streptococci, anaerobic bacteria, and polymicrobial infections may occur.[54]

PATHOGENESIS

Direct bacterial invasion of the umbilical cord and surrounding skin is common. Bacteria can invade the umbilical artery and spread across its lumen, causing necrosis of the loose connective tissue of the arterial wall. If the umbilical and iliac ends are occluded, a septic, loculated focus of infection may be found. When the umbilical end remains patent, purulent material may drain through the umbilicus. If the connective tissue of the artery is extensively involved, peritonitis can develop, or the infection can extend along its course and manifest as a scrotal or deep thigh abscess. If the iliac end of the artery is patent, but the umbilical end is sealed, septicemia can ensue.

CLINICAL MANIFESTATIONS

Purulent drainage can be noted from the umbilical stump at its base of attachment to the abdominal wall or from the navel after the cord has separated. The discharge can be foul smelling. Periumbilical erythema and induration may be noted. If extensive periumbilical edema or involvement of the abdominal wall is noted, the complication of necrotizing fasciitis should be considered.

DIAGNOSIS

Gram stain and culture for aerobic and anaerobic bacteria should be performed on the purulent material from the umbilical stump. Whenever septic umbilical arteritis is suspected, blood cultures should be obtained.

TREATMENT

Otherwise well-appearing infants who have moist or "smelly" cords, but no periumbilical erythema, edema, or exudate often respond to local measures. The exception is omphalitis caused by group A streptococci, which requires parenteral penicillin therapy. Parenteral administration of antibiotics is indicated if a neonate presents with periumbilical erythema, edema, and tenderness with or without purulent drainage. Combination therapy should be administered to provide broad-spectrum coverage. Vancomycin should be provided for gram-positive coverage. An aminoglycoside, or perhaps a third-generation cephalosporin for better tissue penetration, can be given for gram-negative coverage. The presence of crepitus or black discoloration of the periumbilical tissues suggests an anaerobic or mixed infection. In that case, consideration should be given to adding clindamycin or metronidazole for anaerobic coverage. Necrotizing fasciitis requires extensive surgical débridement and pathogen-directed antibiotic therapy and supportive care.

COMPLICATIONS

Omphalitis complicated by necrotizing fasciitis can be associated with bacteremia, coagulopathy, and shock, and frequently progresses to death despite heroic surgical and supportive measures. Septic embolization with metastasis to the lungs, kidneys, and skin can occur. Other infections complicating or occurring in the absence of cutaneous signs of omphalitis include pyelophlebitis (suppurative thrombophlebitis of portal or umbilical veins), liver abscess, septic umbilical arteritis, endocarditis, and subacute necrotizing funisitis.[20]

Mastitis (Breast Abscess)

Neonatal mastitis is most commonly caused by *S. aureus*. Infection with other organisms has been described, including *E. coli, Pseudomonas, Proteus, Salmonella,* GBS, and anaerobes. The incidence is low; in one center, only 21 cases of neonatal mastitis or breast abscess were seen in a 7-year period.[17]

Mastitis rarely develops during the first week of life, but is seen more frequently during the second and third weeks after birth. A preponderance of female infants has been observed when mastitis occurs beyond the second week of life. Breast abscesses are rare in premature neonates, presumably because of underdevelopment of the mammary glands. Infection probably results from invasion of the duct system of the breast by skin flora. The breast can be enlarged, erythematous, and tender, but is more likely to be firm than fluctuant. Systemic signs and symptoms are uncommon; only one fourth of infants have a low-grade fever. The disorder must be distinguished from enlargement that is physiologic or hormonally induced; hormonally induced cases more likely produce swelling bilaterally.

Aspiration of the abscess for Gram stain and culture and blood culture are indicated. If gram-positive cocci are seen on the Gram stain, vancomycin or clindamycin should be given until the results of susceptibility testing are available. An aminoglycoside or cefotaxime is indicated when gram-negative bacilli are present. If no organisms are noted on Gram stain, vancomycin or clindamycin and either an aminoglycoside or cefotaxime should be given pending culture results. Surgical incision and drainage may be necessary and should be performed by an experienced surgeon to minimize scarring of breast tissue.

Parotitis

Suppurative parotitis is a rare infection in newborns; only 32 cases have been described in English since 1970.[59] More than one third of the infants were born prematurely, and the causative organism in most cases was *S. aureus*. Infection is likely caused by the ascent of microorganisms from the oral cavity through the Stensen duct in the setting of salivary stasis or by invasion with blood-borne organisms. Dehydration has been noted before the onset of infection in some patients. Typically, infants present in the second week of life with parotid gland swelling and fever. The swollen parotid gland is accompanied by an area of erythema in the overlying skin. The gland may be tender, warm, firm, or fluctuant. Purulent material can drain spontaneously or be expressed from the Stensen duct. Septicemia may accompany localized infection.

The diagnosis is made by Gram-stained smear and culture of purulent material expressed from the duct or obtained by percutaneous aspiration of a fluctuant area of the parotid gland. A blood culture should obtained. Incision and drainage should be performed if the lesions are fluctuant. Empirical systemic antibiotic treatment should provide coverage for *S. aureus, E. coli,* and *Pseudomonas*. If the cultures are sterile, or the infant fails to respond to antimicrobial therapy, or both, addition of an antibiotic with anaerobic activity should be considered. Surgical drainage may be required if clinical improvement is not apparent within 48 hours. Complications include salivary fistulas, facial palsy, mediastinitis, and extension into the external auditory canal. Involvement of another salivary gland (most often the other parotid) or septicemia occasionally complicates cases of acute parotitis. The disease must be differentiated from infections of the maxilla and from lymphangiomas and hemangiomas.

MISCELLANEOUS BACTERIAL INFECTIONS

Anaerobic Infection

INCIDENCE

The true incidence of neonatal anaerobic bacteremia is difficult to ascertain. Surveys in the 1960s and 1970s suggested that anaerobic bacteria were the causative agents in one fourth of all neonatal bacteremias. A later retrospective review suggests that neonatal anaerobic bacteremia is less common even in the setting of significant gastrointestinal disease.[43] Anaerobes accounted for only 1% of isolates causing neonatal sepsis from 1989-2003 in another review.[9]

ETIOLOGY

With the exceptions of *Clostridium botulinum* and *Clostridium tetani,* most anaerobic bacteria are part of the normal flora of the gastrointestinal tract, the genital tract, or the skin, and can be potential neonatal pathogens. Gram-positive anaerobes associated with clinical disease in patients of any age include *Peptococcus, Peptostreptococcus,* microaerophilic streptococci, *Clostridium* species, *Propionibacterium,* and *Eubacterium*. Clinically significant gram-negative anaerobes include *Bacteroides fragilis,* other *Bacteroides* species, *Fusobacterium, Veillonella,* and *Prevotella melaninogenica*.

PATHOGENESIS

Anaerobic infections occur in association with aspiration, gastrointestinal ischemia or perforation, trauma, and tissue necrosis—events that have been associated with complicated deliveries or premature infants who are critically ill. Obstetric and neonatal factors associated with increased risk of sepsis neonatorum, including prolonged ROM, maternal chorioamnionitis, prematurity, and respiratory distress, are also risk factors for anaerobic sepsis.

CLINICAL MANIFESTATIONS

The signs and symptoms of anaerobic septicemia or peritonitis are indistinguishable from those described for other forms of neonatal septicemia or peritonitis. Neonatal anaerobic bacteremia occurs in two distinct settings. In the first 3 days of life, anaerobic bacteremia is associated with perinatal sepsis and chorioamnionitis, suggesting vertical transmission. In older neonates, anaerobic bacteremia is associated with a gastrointestinal process, including appendicitis, necrotizing enterocolitis, or other causes of ruptured viscus. The bacteria isolated vary, depending on the clinical setting. Gram-positive anaerobic bacteria susceptible to penicillin G were isolated from blood cultures from 8 of 12 neonates with sepsis in the first 48 hours of life, whereas 11 of 17 neonates older than 2 days of age with clinical evidence of necrotizing enterocolitis had penicillin-resistant, gram-negative anaerobes isolated from blood cultures.[43] This study suggests that gram-positive anaerobic bacteria are more frequently associated with early-onset sepsis and gram-negative anaerobes with gastrointestinal disease. The exception was observed in congenital pneumonia occurring in the absence of chorioamnionitis; *Bacteroides* was frequently isolated from blood cultures from these infants. Anaerobic infection caused by *Clostridium* can manifest as systemic illness or localized infection, such as cellulitis, omphalitis, or necrotizing fasciitis.

DIAGNOSIS

The diagnosis of anaerobic infection should be considered in neonates with clinical signs suggestive of sepsis associated with prolonged ROM, chorioamnionitis, intestinal perforation, or tissue necrosis. Anaerobic culture media are necessary to optimize recovery of these organisms. Use of an anaerobic transport tube or a sealed syringe is recommended for collection of clinical specimens.

TREATMENT

The choice of antibiotic therapy depends on the etiologic agent. Susceptibility testing for anaerobic bacteria is technically difficult and not readily available. Generally, penicillin is active against most gram-positive and some gram-negative anaerobic microorganisms. *Bacteroides* species of the gastrointestinal tract usually are penicillin-resistant. Because *B. fragilis* is commonly isolated from peritoneal fluid in newborns with intestinal perforation or necrotizing enterocolitis, anaerobic coverage is appropriate in those settings. *Bacteroides* species are predictably susceptible to metronidazole and sometimes to clindamycin. Metronidazole is favored over clindamycin for treatment of meningitis or when clindamycin resistance is a concern. A beta-lactam penicillin combined with a beta-lactamase inhibitor, such as piperacillin-tazobactam, can be useful for treatment in some infants.

PROGNOSIS

The reported case-fatality rate for neonatal anaerobic septicemia varies from 4% to 45%.

Infant Botulism

INCIDENCE

Infant botulism was first recognized in the United States in 1976, and more than 1500 cases have been confirmed since then. Cases have been reported from many countries and from most regions of the United States. The greatest proportion of cases have occurred in California and the eastern Pennsylvania–New Jersey–Delaware area.[34] The onset of illness peaks between 2 and 4 months of age, although disease occurring in the second week of life has been described. More than 90% of patients are younger than 6 months of age. The actual incidence is difficult to determine because most mildly ill infants go unrecognized, and many severely affected infants die suddenly and can be misdiagnosed as having sudden infant death syndrome.

ETIOLOGY

Infant botulism is caused by *C. botulinum,* a ubiquitous, gram-positive, spore-forming, toxin-elaborating obligate anaerobe. Seven serologically distinct types of toxin have been identified (types A to G), but disease in the United States has been caused almost exclusively by toxin A or B. *Clostridium barati* and *Clostridium butyricum,* other species of *Clostridium,* elaborate neurotoxins similar to botulinum toxin and have been associated with infant botulism in rare cases. *C. botulinum* spores have been found worldwide in soil, water, agricultural products, and honey. Although extensive epidemiologic studies have been performed, no single source has been identified.

PATHOGENESIS

Classic botulism follows ingestion of botulinal spores. Infant botulism occurs when ingested *C. botulinum* spores germinate in the intestine, releasing bacteria that colonize the colon and produce botulinum neurotoxin. Systemically absorbed toxin binds irreversibly to ganglionic and postganglionic cholinergic synapses, preventing release of acetylcholine. Clinical manifestations include motor weakness in peripheral and cranial nerve distributions and autonomic instability.

Studies in a murine model suggest that infants at particular risk for development of botulism transiently lack competitive microbial intestinal flora, or that alterations in motility or pH permit overgrowth of vegetative forms of ingested spores. Infants who have been exclusively breastfed and recently weaned are an at-risk group for botulism. Formula-fed infants with disease are hospitalized at a younger age than are breast-fed infants (7.6 weeks versus 13.7 weeks).

CLINICAL MANIFESTATIONS

The clinical features associated with infant botulism range from mild disease to sudden death. Most recognized cases require hospitalization. The onset can be insidious or fulminant. The symptoms for which most parents seek medical attention are lethargy, poor feeding, and progressive weakness. In retrospect, most parents acknowledge, however, that the infant has been constipated. Typically, the infant is afebrile unless a secondary infection has occurred. Other than hypotonia and weakness, the results of physical examination can be normal early in the course. Cranial nerve palsies soon develop and can manifest as poor head control, ptosis, expressionless facies, and weak cry. Airway protection becomes compromised if gag, swallow, and suck reflexes are impaired. Progressive descending symmetric flaccid paralysis can ensue. Deep tendon reflexes can be normal, but often become diminished or absent as the paralysis progresses. Paralysis of respiratory muscles can be complicated by aspiration pneumonia. Generalized weakness and hypotonia can persist for 1 to 3 weeks without evidence of improvement.

DIAGNOSIS

The diagnosis of infant botulism should be considered in any infant presenting with hypotonia, constipation, and poor feeding. Confirmation of the diagnosis requires isolation of *C. botulinum* or its toxin from the stool. The organism and occasionally the toxin can be isolated from stool for prolonged periods. Special culture techniques using enrichment and selective media are necessary to isolate *C. botulinum*. Toxin neutralization bioassay in mice performed on stool filtrate at a state laboratory or the CDC is the only reliable confirmatory test. A stool specimen for toxin assay is the test of choice for infant botulism.[34]

While awaiting the results of stool studies, a presumptive diagnosis can be made in infants with clinical features suggesting disease if typical findings are noted on electrodiagnostic studies. Nerve conduction study results are normal, but electromyography reveals abnormal spontaneous activity at the motor endplate with abundant brief, small-amplitude motor unit action potentials.

TREATMENT

A single dose of human-derived botulinum antitoxin, known as botulism immune globulin intravenous (BIG-IV) is efficacious in reducing hospitalization from 5.5 to 2.5 weeks and reducing by two thirds the rate of intubation required.[34] The U.S. Food and Drug Administration (FDA) licensed

BIG-IV for treatment of infant botulism in 2003. It now is under the proprietary name of BabyBIG and is available through the California Department of Health Services (510-540-2646) for treatment of botulism caused by types A or B *C. botulinum*.[35] BIG-IV should be administered as early as is feasible in the course of the disease to interrupt neuromuscular blockade.

Meticulous supportive care is also a mainstay of therapy. The goal is to provide nutritional and respiratory support, while avoiding potential complications. Patients should not be fed by mouth until adequate gag reflex and swallowing are observed. Gavage feeding can supply the necessary nutritional intake. Parenteral hyperalimentation may be necessary because normal bowel motility may not return for several weeks. Respiratory and cardiovascular status should be monitored closely. Intubation may be required for airway protection and respiratory failure. The average duration of hospitalization is approximately 1 month.

Antibiotics are not beneficial and can exacerbate the disease process by causing the release of neurotoxin into the gut when bacteria are killed. Antimicrobial therapy is indicated for treatment of pneumonia or urinary tract infection that may develop. The use of aminoglycoside antibiotics should be avoided because of the possibility of potentiation of neuromuscular blockade.

PROGNOSIS

Because the toxin binds irreversibly to the motor endplates, regeneration of nerve endings and their neuromuscular junctions is necessary for recovery. This often requires several weeks. Some centers have described relapse after initial improvement. A small percentage of infants have recurrence of symptoms after discharge home. No predictors of relapse are recognized. The case-fatality rate is estimated to be less than 2% for hospitalized patients.

Listeriosis

INCIDENCE

Listeria monocytogenes can produce disease in healthy individuals, but infection is more prevalent in pregnant women, neonates, and immunocompromised hosts. A population-based surveillance study by the CDC showed a geographic variation in the incidence of neonatal listeriosis. In the year after a large outbreak in California, the incidence was 24.3 per 100,000 live births in Los Angeles County, whereas in the rest of the United States, the incidence was 7.5 per 100,000 live births.

MICROBIOLOGY

Listeriosis is caused by *L. monocytogenes,* a nonsporulating, β-hemolytic, short, gram-positive bacillus. It is an intracellular pathogen and can be observed in polymorphonuclear leukocytes on Gram-stained smears of infected body fluids. *Listeria* is similar morphologically to diphtheroids and can be overlooked as a contaminant. *Listeria* organisms decolorize readily during the Gram-staining procedure and have been mistakenly identified as gram-negative organisms, including *Haemophilus.*

PATHOGENESIS

Listeria has been recovered from soil, sewage, and decayed vegetation. It is a well-known cause of sheep and cattle epizootics. Most non-neonatal human infections are acquired after ingestion of contaminated foods such as unpasteurized milk, soft cheeses, raw meat, and vegetables. Several epidemics of listeriosis in the general population have been reported in pregnant women and their offspring in association with consumption of Mexican-style soft cheese. Family contacts of patients with listeriosis can be colonized in their gastrointestinal tract.

Maternal disease is most frequently documented in the third trimester of pregnancy, probably in association with the decline in cell-mediated immunity that occurs at 26 to 30 weeks of gestation.[48] Infection acquired early in pregnancy can lead to abortion and, if acquired later, to stillbirth or premature labor and delivery. Transplacental transmission is believed to be the most significant mechanism for acquiring early-onset disease, although ingestion or aspiration of infected amniotic fluid before delivery and aspiration of infected secretions during delivery are possible.

The development of late-onset disease usually is not associated with symptomatic maternal infection. Transmission can be vertical from a colonized but asymptomatic mother or from other colonized or infected caregivers, or it can be nosocomial.

The distribution of *Listeria* serotypes from neonates with early-onset and late-onset disease differs. Early-onset disease is predominantly associated with serotypes Ia and Ib and occasionally IVb, whereas late-onset disease is associated most frequently with serotype IVb. Serotyping is useful in epidemiologic studies, but is not important clinically.

CLINICAL MANIFESTATIONS

The signs and symptoms of early-onset and late-onset disease are indistinguishable from signs and symptoms seen in other neonatal bacterial infections. In early-onset disease, the mother often has symptoms of a flulike illness before onset of labor. *Listeria* is frequently isolated from blood cultures obtained from febrile mothers. Evidence of neonatal infection is apparent in most infants at or soon after birth. Many appear meconium stained, even infants born before 32 weeks' gestation, and this is the result of a green-brown staining of the amniotic fluid. Sepsis and pneumonia are the most frequently observed clinical syndromes. Neonates can present with anorexia, lethargy, vomiting, respiratory distress, apnea, cyanosis, and a papular, pustular, or petechial rash.

Late-onset listeriosis most commonly manifests as meningitis. Fever and irritability can be present. The onset is often insidious.

DIAGNOSIS

A maternal history of stillbirth or repeated spontaneous abortions should prompt a high index of suspicion for listeriosis. Blood and CSF cultures should be obtained in all infants. *Listeria monocytogenes* isolated from cultures of the maternal amniotic fluid or placental tissue when infants have early-onset sepsis supports the diagnosis. Aspirates or biopsy specimens of the rash can reveal the organism.

CSF findings in cases of *Listeria* meningitis are characteristic of bacterial meningitides, with a predominance of polymorphonuclear leukocytes, an elevated protein concentration, and a depressed CSF glucose concentration. An increased number of mononuclear cells can be seen in CSF from some infants. On Gram stain, the organisms may be gram-variable and may look like diphtheroids, cocci, or diplococci. A peripheral leukocytosis with left shift, neutropenia, or thrombocytopenia can be observed. Anemia, possibly related to the production of hemolysin, is occasionally present.

TREATMENT

Cephalosporins have no activity against *Listeria*. Ampicillin is the first line of therapy. An aminoglycoside together with ampicillin is synergistic in vitro and in animal models of infection, and is suggested for initial treatment of neonatal infection. After clinical response occurs, ampicillin alone can be given for less severe infections. Treatment should be continued for approximately 14 days in uncomplicated infections. Repeat lumbar puncture should be performed at 24 to 48 hours after the start of treatment to document CSF sterilization.

PROGNOSIS

The case-fatality rate can approach 50% in early-onset infection with *Listeria*, but is less than 10% if disease occurs after the fifth day of life. In the absence of meningitis or other CNS complications, the prognosis is good even in premature infants. CNS sequelae can be observed in some infants after meningitis, but the prognosis has not been extensively studied.

Syphilis

INCIDENCE

The incidence of congenital syphilis parallels that of primary and secondary disease in women. The last national syphilis epidemic, which was followed by a congenital syphilis epidemic, occurred during the late 1980s and early 1990s. Congenital syphilis rates have declined yearly since 1991. During 2000-2002, the rate of congenital syphilis decreased 21% to 11.2 cases per 100,000 live births.[14] Lack of prenatal care and limited prenatal care are risk factors for congenital syphilis.

MICROBIOLOGY

Syphilis is caused by *T. pallidum*, a tightly coiled, motile spirochete. It is too narrow to be visualized by conventional light microscopy (0.09 to 0.18 μm wide × 5 to 15 μm long), but can be detected on dark-field microscopy. It can be propagated in animal models of infection, but has not been cultured in vitro.

PATHOGENESIS AND PATHOLOGY

Transmission of congenital syphilis is most frequently transplacental, although infection can be acquired by contact with genital lesions during delivery. Transplacental infection can occur at any stage of pregnancy and during any stage of maternal syphilis. Infants are more likely to become infected, however, if the mother had primary or secondary syphilis during pregnancy than if she acquired syphilis months or years before conception. The risk of fetal infection also increases with advancing gestational age. If early gestational infection is not recognized, potential outcomes include miscarriage, stillbirth, premature delivery, or neonatal death. Approximately 30% to 40% of fetuses with congenital syphilis are stillborn. Mothers of infants with congenital syphilis should have testing performed for other sexually transmissible infections, such as hepatitis B and hepatitis C, *Chlamydia*, human immunodeficiency virus (HIV), and gonococcal infection.

Previously, it was believed that fetal infection did not occur before 18 weeks' gestation. It is now known that early gestational infection can occur, but because of fetal immunoincompetence, the pathologic changes in fetal tissues are not observed until after the fifth month of gestation. The infection disseminates hematogenously from the placenta to the fetus, so diffuse involvement is common. The pathologic changes observed in congenital syphilis resemble the changes seen in acquired disease. Fibrosis and obliterative endarteritis with histiocytic, plasmacytic, and lymphocytic perivascular infiltrates are typical findings present in most affected organs. Examination of the placenta and the umbilical cord can assist in the diagnosis of congenital disease. Histologic examination reveals focal villositis with endovascular and perivascular proliferation in the placenta and necrotizing funisitis on umbilical cord sections. Spirochetes may be visible on silver-stained specimens of the placenta or umbilical cord.

CLINICAL MANIFESTATIONS

Congenital syphilis is classified into early and late stages based on age at onset. Early congenital syphilis occurs before 2 years of age and represents active infection and inflammation. Approximately two thirds of infected infants are asymptomatic at birth. A wide spectrum of clinical manifestations can be seen in symptomatic infants (Box 39-4). Most symptomatic infants have hepatosplenomegaly and bone changes on radiographs, and many are anemic. The enlarged liver is believed to be related to extramedullary hematopoiesis. A diffuse hepatitis with elevated aminotransferases and direct and indirect hyperbilirubinemia can be seen. Skeletal manifestations include metaphyseal osteochondritis, periostitis, and osteitis. Osseous destruction of the proximal medial tibial metaphysis (Wimberger sign) can be observed (Fig. 39-11). Symptomatic infants are more likely to have spirochetal invasion of the CNS, but laboratory evidence of CNS involvement is not always apparent.

Late manifestations reflect the body's response to early infection or to persistent inflammation. Cutaneous, dental, skeletal, ocular, auditory, and CNS involvement can occur (Box 39-5). The most frequently observed signs include frontal bossing, saddle nose deformity, short maxilla with high-arched palate, and Hutchinson triad.

DIAGNOSIS

As noted by Ingall and colleagues,[29] congenital syphilis should be considered in the differential diagnosis of any newborn with unexplained prematurity, hydrops fetalis of unknown etiology, or placental enlargement. An infant with persistent rhinitis; failure to thrive; or unexplained anemia, thrombocytopenia, jaundice, or hepatosplenomegaly should prompt consideration of congenital syphilis.

BOX 39–4 Clinical Findings of Early Congenital Syphilis*

- Nonimmune hydrops fetalis
- Intrauterine growth restriction
- Failure to thrive
- Generalized lymphadenopathy
- Bone abnormalities
  - Periostitis
  - Osteochondritis (Wimberger sign)
  - Osteitis
- Hepatosplenomegaly (with or without elevated aminotransferases, jaundice)
- Mucocutaneous lesions
  - Pemphigus syphiliticus (vesiculobullous eruption, contagious)
  - Maculopapular eruption
  - Mucous patches of palate, perineum, intertriginous areas
  - Condyloma latum
- Persistent rhinitis (snuffles, contagious)
- Pneumonitis (pneumonia alba)
- Nephrotic syndrome
- Neurologic abnormalities
  - Syphilitic leptomeningitis
- Hematologic abnormalities
  - Leukocytosis
  - Leukopenia
  - Anemia, Coombs-negative hemolytic
  - Thrombocytopenia
- Ocular abnormalities
  - Chorioretinitis
  - Uveitis

---

*Defined as age <2 years.

BOX 39–5 Clinical Manifestations of Late Congenital Syphilis*

DENTAL

Hutchinson teeth (notched, peg-shaped upper central incisors)[†]
Mulberry molars (multiple small cusps)

BONE

Frontal bossae of Parrot
Saddle nose deformity
Short maxillae
High-arched palate
Higouménakis sign (sternoclavicular thickening)
Flaring scapulae
Saber shins (anterior bowing of tibia)
Clutton joints (painless synovitis, hydrarthrosis)

CUTANEOUS

Rhagades (linear scars radiating from mouth, nares, and anus)

OCULAR

Interstitial keratitis[†]

NEUROLOGIC

Eighth cranial nerve deafness[†]
Mental retardation
Hydrocephalus
Cranial nerve palsies
Seizure disorder

---

*Defined as age >2 years.
[†] Features of Hutchinson triad.

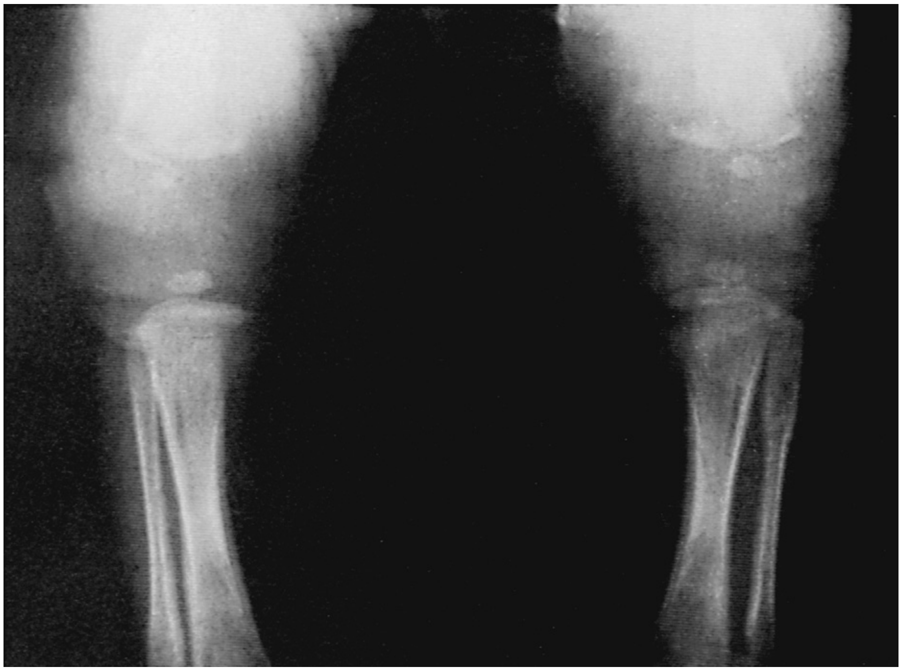

Figure 39–11. Osteochondritis and periostitis of the bones in both lower extremities of a patient with congenital syphilis. The radiolucent area seen at the medial aspect of the proximal tibial metaphyses is known as the Wimberger sign; the zone of translucency visible proximal to the epiphyseal ends of both tibias is called the Wegner sign.

T. pallidum cannot be cultured in vitro. Treponemes can be detected by dark-field examination or direct fluorescent antibody staining of material from mucocutaneous lesions, the umbilical cord or placenta, amniotic fluid, nasal discharge, or postmortem tissue.[51] More commonly, the diagnosis is suggested by the history or clinical and radiographic findings, or both, and confirmed by serologic testing. Serologic tests for syphilis (STS) include nontreponemal and treponemal antibody tests. Nontreponemal tests, such as the rapid plasma reagin test or the Venereal Disease Research Laboratory (VDRL) test, use a purified cardiolipin and lecithin antigen to detect reagin, a nonspecific antibody produced in response to *T. pallidum* infection. Biologic false-positive results can be seen with nontreponemal STS in patients with autoimmune disorders. Quantitative titers of nontreponemal tests can be followed to evaluate response to therapy.

Treponemal serologic tests include the fluorescent treponemal antibody absorption test and the *T. pallidum* particle agglutination test. Because both tests remain positive after initial infection, serial titers are not helpful for evaluating response to therapy. A fluorescent treponemal antibody absorption IgM test and a polymerase chain reaction technique for detection of *T. pallidum* in tissues and body fluids have been developed, but are not commercially available.

An infant should be evaluated for congenital syphilis when the maternal titer has increased fourfold, if the infant's titer is fourfold greater than the mother's, or if the infant is symptomatic. In addition, if born to a mother with positive nontreponemal and treponemal tests, the infant should be evaluated further if the mother had untreated, inadequately treated, or undocumented treatment for syphilis; if erythromycin was used for treatment during pregnancy; if treatment during pregnancy occurred less than 1 month before delivery; if the expected decrease in nontreponemal antibody has not been documented; or if there is insufficient serologic follow-up to document the response to treatment.

The evaluation of an infant with suspected congenital syphilis should include (1) physical examination; (2) quantitative nontreponemal test of serum (not cord blood) for syphilis; (3) routine CSF evaluation and CSF VDRL; (4) long bone radiographs; (5) complete blood count and platelet count; and (6) other tests, such as chest radiography, as clinically indicated. Criteria for the diagnosis of proven or highly probable congenital syphilis include any of the following: (1) physical, laboratory, or radiographic evidence of active infection; (2) placenta or umbilical cord is positive for treponemes using specific direct fluorescent antibody staining or dark-field test; (3) active CSF VDRL result; or (4) an infant quantitative serum nontreponemal STS titer fourfold or more than that of the mother. A negative nontreponemal STS at delivery does not exclude recent maternal infection that has not yet elicited an antibody response, or has elicited only IgM antibodies that do not cross the placenta.

TREATMENT

Serologic tests on the infant and on the mother during pregnancy and at delivery, maternal antepartum antimicrobial therapy, and the infant's clinical status must be considered before treatment plans can be made. Treatment should be completed before nursery discharge for infants with proven or highly probable disease. It should be considered in infants who are asymptomatic with normal CSF and radiographic examination results under the conditions dictated by the maternal treatment history (Table 39-22).[1]

Jarisch-Herxheimer reactions, manifested by fever, tachypnea, tachycardia, hypotension, prominence of cutaneous lesions, and death, have been reported after initiation of treatment. The cause of this reaction is unknown, although release of endotoxin from the spirochetes has been suggested.

FOLLOW-UP

Infants with reactive nontreponemal STS must have serial quantitative tests after discharge home. Uninfected infants with reactive STS from transplacental transfer of maternal antibody should have a decrease in titer by 3 months of age and a nonreactive test at 6 months. To confirm therapeutic response, treated infants with suspected or proven disease

TABLE 39–22 Recommended Therapy for Neonates (<4 Weeks Old) with Congenital Syphilis[*]

Clinical Status	Treatment
Proven or highly probable disease	Aqueous crystalline penicillin G for 10 days[†]
Normal examination and nontreponemal test the same or less than four-fold the maternal result with maternal treatment history: None, inadequate penicillin treatment[‡]	Aqueous crystalline penicillin G IV for 10-14 days[†] *or* Clinical, serologic follow-up, and benzathine penicillin G IM, single dose[§]
Adequate therapy given >4 wk before delivery; mother has no evidence of reinfection or relapse	Clinical, serologic follow-up, and benzathine penicillin G IM, single dose[¶]

[*] If >1 day is missed, the course should be restarted.

[†] Aqueous crystalline penicillin G 50,000 U/kg IV given every 12 hours for the first 7 days of life and every 8 hours thereafter. Alternatively, procaine penicillin G 50,000 U/kg IM single daily dose for 10 days can be given.

[‡] Maternal treatment is termed inadequate when her penicillin dose is unknown, is undocumented, or was inadequate; if she received erythromycin or other non-penicillin regimen; if treatment was given <4 weeks before delivery; or the response to treatment was not documented by showing a fourfold decrease in titer of a nontreponemal test for syphilis.

[§] Benzathine penicillin G 50,000 U/kg IM. Some experts recommend aqueous crystalline penicillin G for proven or highly probable disease.

[¶] Some experts would not treat the infant, but would provide close serologic follow-up.

Adapted from American Academy of Pediatrics: Syphilis. In Pickering LK et al, editors: *Red Book: 2009 report of the Committee on Infectious Diseases,* 28th ed, Elk Grove Village, IL, American Academy of Pediatrics, p 645.

should have quantitative nontreponemal STS titers at 2 to 4 months, 6 months, and 12 months after completion of therapy, or until the test becomes nonreactive or the titer has decreased by fourfold. Retreatment should be considered for any child with persistent, unchanging nontreponemal STS titers.

CSF evaluations at 6-month intervals, in addition to serial serum quantitative nontreponemal titers, are recommended for infants with congenital neurosyphilis. Retreatment should be undertaken if the CSF VDRL is positive at 6 months of age.

Treatment of asymptomatic infected infants in the first 3 months of life usually prevents development of late stigmata. Late congenital syphilis can develop if congenital infection goes unrecognized and untreated. Stigmata of late congenital syphilis can develop in infants symptomatic at birth despite appropriate treatment in the neonatal period.

PREVENTION

Routine prenatal screening and penicillin therapy of infected women and their partners can prevent congenital syphilis. Prenatal screening consisting of nontreponemal STS in the first trimester and at delivery is recommended. Another test at the beginning of the third trimester should be considered in areas with a high prevalence of syphilis. Screening of the mother at delivery, in addition to the infant, is recommended to avoid potential false-negative infant serologic test results related to low antibody concentrations.

Tetanus Neonatorum

INCIDENCE

Tetanus neonatorum is rare in the United States, but remains a significant cause of neonatal morbidity and mortality in developing countries.

MICROBIOLOGY

Clostridium tetani is a slender, anaerobic, spore-forming, gram-positive bacillus. *C. tetani* is present in soil and can be found in human and animal feces. Risk factors associated with the higher incidence in developing countries include lack of maternal immunization against tetanus, childbirth under unhygienic conditions, use of contaminated umbilical stump dressings, and rituals involving the application of manure to the umbilicus.

PATHOLOGY

No specific pathologic lesions are attributed to this infectious agent, although changes in the brain and spinal cord have been described in patients dying of tetanus.

PATHOGENESIS

The signs and symptoms of tetanus are the result of toxin production, rather than invasive infection. The umbilical stump contaminated by soil or feces can serve as a portal of entry for the spores. When the spores germinate, the bacteria produce two toxins: tetanolysin, which hemolyzes red blood cells in vitro, but does not seem to be important in vivo, and tetanospasmin. Tetanospasmin is second only to botulinum toxin in potency. By inhibiting release of acetylcholine, it interferes with neuromuscular transmission, resulting in muscular contractions. Tetanospasmin affects the motor endplates of skeletal muscle, the spinal cord and brain, and occasionally the sympathetic nervous system. When toxin becomes fixed to nervous tissue, it cannot be neutralized by antitoxin. The mechanism by which the toxin reaches the CNS is unclear. Transportation within the nerves is likely. The incubation period ranges from 2 to 21 days.

CLINICAL MANIFESTATIONS

The clinical syndrome differs from that seen in older children and adults. Most infants are irritable and show diminished suck and cessation of crying. Fever is often noted at presentation. The disease progresses to generalized rigidity with muscle spasms and seizures. Flexor spasms are exacerbated by stimulation. Some infants become cyanotic if the spasms are prolonged. Testing of deep tendon reflexes usually shows hyperreflexia. Extreme flexion of the toes is frequently observed. The hallmark of tetanus in older patients is lockjaw, also referred to as risus sardonicus. Lockjaw does not develop in most infants, but severe reflex spasms of the masseter muscles do occur if the jaw is moved for feeding.

Cardiorespiratory difficulties, including tachycardia, tachypnea, cyanosis, or apnea, can be observed. Laryngoglottal spasm can predispose to aspiration pneumonia. Pulmonary processes such as bronchopneumonia or hemorrhage are a frequent cause of death in neonatal tetanus.

DIFFERENTIAL DIAGNOSIS

Cultures of the blood and the wound (umbilical stump) are invariably sterile. Diagnosis is made by clinical presentation and exclusion of other possibilities. Infants can be misdiagnosed as having neonatal seizures.

TREATMENT

Supportive care is essential. Maintenance of a clear airway and provision of adequate ventilation are most important. Meticulous care must be exercised to decrease the likelihood of secondary bacterial pulmonary infections. The bladder may need to be catheterized if it does not empty spontaneously.

Because stimulation can precipitate spasms and seizures, timing of medical interventions should be coordinated, and exposure to nonessential external stimuli should be limited. Diazepam is an effective agent in controlling the tonic spasms of tetanus. Barbiturates may be helpful as an adjunct to therapy and may help sedate the patient.

Metronidazole should be given for a 10- to 14-day course to decrease the number of vegetative forms of *C. tetani* and is the treatment of choice. Penicillin G is an alternative antibiotic. Human tetanus immune globulin given intramuscularly in a single dose is recommended to neutralize circulating unbound toxin. Débridement of the entry site, an essential component of therapy in adult disease, is performed in some cases of neonatal tetanus, but wide excision is not indicated.

PREVENTION

A well-immunized mother offers the best protection against tetanus neonatorum. Because antitoxin crosses the placenta, infants born to mothers whose tetanus immunizations are current should have adequate antitoxin antibody concentrations. Aseptic obstetric and neonatal care minimizes the likelihood of introduction of *C. tetani* spores. Infants who recover from disease require routine tetanus immunizations because disease does not usually confer immunity.

Tuberculosis

INCIDENCE

Since the early 1990s, the incidence of tuberculosis in the United States has increased, especially among women of childbearing age. Perinatal tuberculosis is uncommon, but management of an infant born to a mother with tuberculous infection is common.

MICROBIOLOGY

Mycobacterium tuberculosis is the causative agent of tuberculosis. *M. tuberculosis* is a slow-growing, obligately aerobic, acid-fast bacillus (AFB). Neonatal infections with other strains of mycobacteria are uncommon. *Mycobacterium bovis* infections were occasionally seen before pasteurization of milk became standard. Neonatal infection with atypical or environmental mycobacteria is rare.

PATHOGENESIS AND PATHOLOGY

Infected mothers can transmit infection to their fetus transplacentally if primary tuberculous infection (asymptomatic or miliary) is acquired during pregnancy, or if the mother has tuberculous endometritis.[60,62] Postpartum transmission can occur if the mother has active pulmonary tuberculosis with cavitation. Neonatal tuberculosis can be acquired intrapartum from ingestion or aspiration of infected secretions and postnatally by inhalation of infected droplets. Before aseptic technique was routinely used, transmission from contamination of the skin or mucous membranes during circumcision was described.

The most common mode of transmission for perinatal disease is inhalation of infected droplets (Table 39-23). Coinfection with HIV increases the risk of extrapulmonary disease, and mothers with extrapulmonary tuberculosis, including pleural effusions, and endometrial, miliary, or meningeal disease are more likely to transmit infection to the fetus. Many infants born to infected mothers do not contract disease, however.

Primary complex formation in the porta hepatis of the liver occurs with congenital infection transmitted hematogenously. Miliary tubercles can be found in the spleen, bone marrow, lung, kidney, adrenal glands, and brain. Gross or microscopic placental lesions may be detected. Primary complex formation in the lung can reflect hematogenous spread, aspiration of infected amniotic fluid or vaginal secretions, or postnatal inhalation.

CLINICAL MANIFESTATIONS

Signs and symptoms of congenital tuberculosis are vague. Some infants may be symptomatic at birth, whereas others do not develop symptoms until late in the first month of life.[38] The appearance on chest radiographs frequently is abnormal. Many infected newborns are premature and have hepatosplenomegaly, respiratory distress, fever, reluctance to feed, and lethargy. Miliary tuberculosis, lymphadenopathy, and otitis media with tympanic membrane perforations, otorrhea, and facial nerve palsy can be seen as well. Meningitis, pleural effusions, and pulmonary cavitations are unusual.

Neonatal tuberculosis is manifested by fever, vomiting, cough, tachypnea, and weight loss. Hepatosplenomegaly occasionally occurs. Unless hepatic primary complex formation is present, it is often difficult to distinguish congenital from neonatal tuberculosis.

DIAGNOSIS

The diagnosis of tuberculosis can be established by demonstration of organisms on AFB smears and growth of *M. tuberculosis* in special culture media. The infant should have a tuberculin skin test (TST), a chest radiograph, and AFB stains and cultures of CSF and gastric and tracheal aspirates. The infant's TST is usually nonreactive even in the presence of active disease. Because treatment of an infected infant does not prevent the skin test from becoming reactive, repeat skin testing should be performed 3 months later if the initial skin test is negative. Other sites that can yield AFB growth include lung or liver tissue, lymph node, middle ear fluid, urine, and bone marrow aspirate.

TREATMENT

Because perinatal tuberculosis is uncommon, the safety and efficacy of antituberculous agents in neonates have not been determined. Standard therapy for older infants consists of

TABLE 39–23 Perinatal Transmission of Tuberculosis

Maternal Focus of Infection	Mode of Spread	Timing	Relative Frequency
Pneumonia with cavitary lesion*	Inhalation of infected droplets	Postnatal	Most common
Amniotic infection after rupture of placental caseous lesion	Aspiration or ingestion of infected fluid	Congenital or intrapartum	Less common
Placentitis after miliary or endometrial tuberculosis	Hematogenous through umbilical vein	Congenital	Rare
Cervicitis	Direct contact, aspiration, or ingestion	Intrapartum	Rare
Mastitis	Ingestion of infected milk	Postnatal	Extremely rare

*Any caregiver with cavitary pulmonary tuberculosis can transmit infection to the infant.

isoniazid, rifampin ethambutol, and pyrazinamide daily for 2 months followed by twice-weekly therapy with isoniazid and rifampin alone (Table 39-24).[61] An aminoglycoside is also initiated when treating potentially life-threatening disease, such as meningitis, until susceptibility testing is completed. The duration of therapy is 6 months in older children without meningitis. The optimal duration has not been determined for neonates, but prolonged treatment has been suggested because of potential neonatal immunoincompetence.

Corticosteroids have been used in tuberculous meningitis to reduce inflammation and decrease intracranial pressure and in endobronchial disease to reduce tracheal compression. Appropriate antituberculous agents must be administered concurrently with steroid therapy to avoid dissemination of infection.

The case-fatality rate for congenital tuberculosis is approximately 50%. Most deaths are related to undiagnosed and untreated disease. The prognosis is worse for premature infants than for term infants with congenital infection.

MANAGEMENT OF INFANTS BORN TO MOTHERS WITH POSITIVE PURIFIED PROTEIN DERIVATIVE SKIN TESTS

Regardless of the mother's clinical status, symptomatic newborns should have a thorough investigation for bacterial sepsis and tuberculous disease. Chest radiograph; CSF examination; blood and CSF bacterial cultures; and mycobacterial stains and cultures of CSF, gastric aspirates, and tracheal aspirates should be obtained. Decisions on antituberculous treatment of the infant should be based on the mother's status and on the results of the infant's evaluation.

For asymptomatic neonates, investigation and treatment are guided by the mother's clinical status. If a mother with a positive TST is clinically well, has a negative chest radiograph, and is not believed to have active disease, no intervention is necessary, provided that the household contacts have been investigated, and active disease has been excluded. Mothers with an abnormal appearance on chest radiograph must have an investigation for tuberculosis, including AFB stains and cultures of sputum and testing for HIV infection. Separation of the mother and the infant is recommended until the mother and infant have been evaluated; if tuberculosis disease is suspected, until the mother and infant are receiving appropriate antituberculous therapy, the mother wears a mask and understands and expresses her willingness to comply with infection control measures.

If there is no evidence of neonatal infection, the infant should be given isoniazid prophylaxis and reevaluated in 3 to 4 months with another TST. Isoniazid can be discontinued at 3 months if the second TST is negative, if the infant is well, and if there is no active infection in the household. Three- or four-drug antituberculous therapy should be started after cultures are obtained if there is evidence of disease in the infant. Bacille Calmette-Guérin immunization of the infant should be considered only in limited and select circumstances, such as if the mother or another household contact has possible multidrug-resistant tuberculosis or has poor adherence to treatment.

PREVENTION OF INFECTION IN THE NEONATAL INTENSIVE CARE UNIT

Barrier Nursing Technique

The use of masks and gowns by nursery personnel does not significantly alter staphylococcal colonization or infection rates in infants. Hand washing, if performed adequately, is

TABLE 39–24 Commonly Used Drugs for Treatment of Tuberculosis in Children

Drug*	Daily† (mg/kg/d)	Twice Weekly† (mg/kg per Dose)	Side Effects	Comments
Isoniazid	10-15; maximum 300 mg	20-40; maximum 900 mg	Mild hepatic enzyme elevation, hepatitis‡, peripheral neuritis, hypersensitivity	Monitor liver function tests monthly
Rifampin	10-20; maximum 600 mg	10-20; maximum 600 mg	Hepatitis‡, vomiting, thrombocytopenia, orange discoloration of secretions	Monitor liver function tests monthly
Pyrazinamide	20-40; maximum 2 g	50-70; maximum 2 g	Hepatotoxicity, hyperuricemia	Monthly uric acid and liver function tests
Streptomycin	20-40; maximum 1 g	20-40; maximum 1 g	Ototoxicity, nephrotoxicity	Monitor renal function, consider hearing test
Ethambutol	15-25; maximum 2.5 g	50; maximum 2.5 g	Optic neuritis, color blindness, decreased visual acuity	Monitor visual fields, visual acuity, and color discrimination frequently

*All drugs may be given PO except streptomycin, which must be given IM.
†See text for details and duration.
‡Incidence of hepatotoxicity increases when isoniazid and rifampin are used together, especially when the isoniazid dosage exceeds 10 mg/kg/d.
Adapted from Starke JR: Perinatal tuberculosis, *Semin Pediatr Infect Dis* 5:20, 1994.

effective in reducing the incidence of nosocomial nursery infections. A 3% solution of hexachlorophene soap is effective in reducing infection by gram-positive bacteria, and various iodinated preparations, including iodinated chlorhexidine (0.5%), are effective against gram-negative organisms. Studies suggest that alcoholic chlorhexidine hand washing agents are effective against drug-resistant strains of *Enterococcus faecium* and *Enterobacter cloacae*. Physicians should be aware that some organisms, including *P. aeruginosa,* can survive in many antiseptic solutions.

Bathing of Infants

Historically, infants were bathed with hexachlorophene to decrease the risk of gram-positive infections. In the 1970s, infants in France developed a toxic encephalopathy attributed to excessive amounts of hexachlorophene in talcum powder. Subsequent neuropathologic studies in the United States revealed an association between brainstem vacuolar lesions and hexachlorophene baths especially in premature infants. Routine bathing with hexachlorophene was discontinued in the early 1970s after this association was recognized.

The Committee on the Fetus and Newborn of the American Academy of Pediatrics recommends that the first bath be postponed until a newborn is thermally stable. Nonmedicated soap and water should be used. Sterile sponges soaked in warm water can be used. During nursery outbreaks of *S. aureus* infection, hexachlorophene bathing of the diaper area can be undertaken to prevent staphylococcal disease.[21] Surveillance of neonatal infections, prompt isolation and treatment of infected infants, and adequate hand washing should be used to prevent nosocomial infections. Crowding should be avoided, and cohort nursing techniques should be applied whenever possible. Hexachlorophene can still be used as an antibacterial agent by nursery personnel.

Cord Care

The umbilicus is a direct portal of entry to the bloodstream, and serves as a site from which other areas of the skin may become contaminated or colonized. No single method of cord care has proved superior in preventing colonization and the development of omphalitis. Options for cord care include application of alcohol, triple dye (brilliant green, proflavin hemisulfate, and crystal violet), or antimicrobial agents such as bacitracin ointment. Alcohol hastens drying of the cord, but probably is ineffective in preventing cord colonization or omphalitis.

Resuscitation and Ventilatory Equipment

Gram-negative microorganisms, particularly *Pseudomonas, Aeromonas,* and *Serratia,* have been associated with sporadic and epidemic infection in the nursery. Routine cultures of medications, nebulizers, and inhalation therapy equipment should be performed, and equipment should be changed frequently to prevent such infections. Use of umbilical, arterial, and venous catheters for parenteral alimentation also has been accompanied by an increased risk of health care–associated infections. Meticulous care is required in the insertion and care of catheters and in the preparation of intravenous solutions for use in total parenteral alimentation. Administration of fluids should be discontinued if signs of inflammation, thrombosis, or purulence are observed. All apparatus used for intravenous administration should be replaced at intervals to decrease the hazard of extrinsic contamination.

Antibiotic Prophylaxis

The effectiveness of intravenous antimicrobial prophylaxis in newborns has not been proven. Indiscriminate use of antibiotics can result in colonization or infection with drug-resistant strains of bacteria or with fungi. The only role for antimicrobial prophylaxis in newborns is for the prevention of gonococcal ophthalmitis or tuberculous disease.

Immune Globulin

There have been numerous in vitro, animal model, and human studies evaluating the use of IVIG in the prevention of infections. Results of several well-designed human trials using IVIG to prevent nosocomial infections in preterm neonates have been published.[2,36] The results of the large, multicenter, randomized, controlled trial led by Fanaroff and associates[18] revealed no significant decrease in the incidence of nosocomial infections, in the number of days hospitalized, or in mortality rate in the premature infants given IVIG. One possible explanation for the lack of protection against health care–associated infections could be that pooled IVIG does not contain adequate amounts of specific antibody against the most common neonatal nosocomial pathogens—CONS and *Candida* species. Even specific antibody may not be protective against health care–associated infections, however, especially if they are associated with foreign bodies such as indwelling catheters. Administration of an IVIG derived from donors with high titers of antibody to surface adhesins of *S. aureus* and *S. epidermidis* failed to reduce the incidence of staphylococcal bacteremia in premature infants.[16] In the future, development of specific, high-titered immunoglobulin preparations against the specific pathogens may be beneficial in prevention of some neonatal infections.

PART 3

Fungal and Protozoal Infections

Morven S. Edwards

FUNGAL INFECTIONS

Disseminated candidiasis is a frequent infection in infants with very low birthweight (VLBW). Other fungal infections are considerably less common in neonates. The increasing incidence of candidiasis is attributable in part to advances in the life-sustaining care provided by neonatal caregivers. Early recognition of infection is important because untreated infections, especially in infants with VLBW, are associated with considerable morbidity and mortality.

Candida

INCIDENCE

Mucocutaneous, cutaneous, and disseminated candidiasis have been reported in newborns. Systemic candidiasis occurs more frequently in premature infants with VLBW.

MICROBIOLOGY

Candida organisms are saprophytic yeasts that are ubiquitous and are constituents of the normal microbial flora of humans. The yeast, or blastospore form of the fungus, is round or egg-shaped and is important in tissue colonization. All *Candida* species form pseudohyphae that are important in invasion. *Candida albicans* is the predominant species associated with maternally acquired neonatal disease. *Candida parapsilosis* is a common species that can account for one quarter of all cases of invasive fungal infection in infants with VLBW.[8]

Other species, such as *Candida glabrata, Candida lusitaniae, Candida krusei,* and *Candida stellatoidea,* are reported less frequently. No special medium is required for growth of *Candida* in the laboratory.

PATHOGENESIS AND PATHOLOGY

C. albicans can be acquired from the vaginal flora of the mother at delivery or from person-to-person contact after birth. *Candida* usually has low pathogenicity for humans. Congenital cutaneous candidiasis seems to be more common if the pregnancy has been complicated by maternal vaginitis, the presence of an intrauterine device, or cervical cerclage.[42] Fungal colonization occurs on the skin and in the gastrointestinal tract before colonization of the respiratory tract.[22] A prospective study in intubated infants with VLBW suggested that there was an increased risk of systemic infection when infants became colonized in the respiratory tract in the first week of life.[40] Factors that alter host defense or that allow proliferation of the organism can increase the risk of invasion. Broad-spectrum antimicrobial use can expedite overgrowth of *Candida* in the gastrointestinal tract. Newborns in general, and infants with VLBW in particular, have qualitative and quantitative deficiencies in humoral and cellular immunity. The organism produces multiple virulence factors, such as adhesins, proteinases, and phospholipases, that promote attachment and invasion. After penetration of epithelial or endothelial barriers, in this setting, *Candida* can penetrate into lymphatics, blood vessels, and deep tissues, resulting in disseminated infection. Disseminated candidiasis can cause disease in any organ system. *Candida* microabscesses have been described in the liver, spleen, kidneys, heart, brain, eyes, bones, and joints.

CLINICAL MANIFESTATIONS

Clinical manifestations depend on the location and extent of the infection. Acute pseudomembranous candidiasis (thrush) manifests with white, curdlike patches that cover the buccal mucosa, gingiva, and tongue. These membranes can be adherent to underlying tissue and, when removed, reveal a denuded, erythematous, painful base. Severe thrush sometimes results in difficulty feeding, but usually no systemic symptoms are apparent. Thrush is frequently associated with cutaneous perineal infection. *Candida* diaper dermatitis begins with an erythematous vesiculopapular eruption that coalesces, producing large areas with satellite lesions that are surrounded by a fine, white, scaly collarette. These lesions usually are restricted to the intertriginous areas in the groin, but can be noted in any warm, moist area, including the neck, axilla, and antecubital and popliteal fossae. The peak incidence occurs at 3 to 4 months of age (see Chapter 52).

After an ascending in utero infection, generalized cutaneous lesions have been noted at birth in congenital cutaneous candidiasis. This condition typically manifests with intensely erythematous maculopapular lesions on the trunk and extremities that rapidly become pustular and rupture, leaving denuded skin with well-defined, raised, scaling borders.[42] Congenital cutaneous candidiasis is usually a benign, self-limited infection, unless it occurs in an infant weighing less than 1500 g, or is associated with respiratory symptoms, or both. In those circumstances, parenteral antifungal therapy is indicated.

Catheter-associated and systemic candidiasis occur later, at a mean of 30 days of age.[2] Infants with invasive neonatal candidiasis usually have one or more risk factors predisposing to infection (Box 39-6). These risk factors relate to immunologic immaturity, to bypassing of natural barriers, to the use of agents such as broad-spectrum antimicrobials that favor the growth of *Candida* species, and to the supportive care required by infants of VLBW. Prior fungal colonization is an important factor in the development of candidiasis. A blood culture obtained through an indwelling catheter, or peripherally while a catheter is in place, suggests the diagnosis. In catheter-associated fungemia, the blood culture becomes sterile concurrently with initiation of amphotericin B therapy and removal of the indwelling catheter. There is no involvement of distant organs, such as the liver, kidneys, or eye. A brief course of amphotericin B usually suffices for treatment. Catheter removal is mandatory. Failure to remove the colonized catheter promotes dissemination and increases the risk for an adverse outcome, including death.

The presentation of systemic candidiasis in an infant with VLBW is similar to that of bacterial sepsis. Infants also can have an insidious onset of symptoms with respiratory deterioration, enteral feeding intolerance, abdominal distention associated with guaiac-positive stools, temperature instability, hypotension, hyperglycemia, and glucosuria. In contrast to disseminated candidiasis in older children and adults, multiple foci of infection are common in infants with systemic disease. Meningitis occurs in approximately 40% of affected infants. Examination of cerebrospinal fluid (CSF) is mandatory. Renal involvement may manifest as candiduria, multiple renal abscesses, or fungus balls that can cause obstruction to the flow of urine. The latter complication may not become evident until later in the treatment course; renal ultrasonography should be performed at the initiation of treatment for all infants suspected to have disseminated candidiasis and repeated as clinically indicated. The ultrasound

BOX 39–6 Risk Factors for Invasive Candidiasis in Neonates

- Gestational age <32 weeks
- Birthweight ≤1500 g
- Male gender
- Apgar score <5 at 5 minutes
- Intubation/mechanical ventilation
- Placement of indwelling devices
  - Umbilical catheters
  - Peripheral or central venous catheters
  - Urinary catheters
  - Cerebrospinal fluid shunt devices
- Abdominal surgery
- Lack of enteral feeding
- Fungal colonization
- Use of intralipid
- Total parenteral nutrition use
- Corticosteroid use
- Use of histamine type 2 receptor blockers
- Administration of cephalosporins
- Prolonged administration of antibiotics

appearance of fungus balls may persist long after clinical resolution of infection. Surgical management can be required for decompression of obstructive candidiasis and drainage of abscesses.[19]

Endophthalmitis is more likely with prolonged candidemia; it most commonly manifests as retinitis, with fluffy or hard white infiltrates. A dilated retinal examination should be part of the diagnostic evaluation for all infants. Involvement of the liver or spleen with microabscesses; endocarditis among infants with indwelling catheters; and extension of infection to the lungs, bones, or joints occur less frequently. The presentation of bone or joint disease is usually indolent, and involvement may not be evident when amphotericin B is initiated, so a high index of suspicion is important. Percutaneous aspiration of an involved joint or bone at the bedside usually is sufficient to establish the diagnosis, and an open drainage procedure is rarely, if ever, required.

DIAGNOSIS

The diagnosis of systemic candidiasis is established by growth of *Candida* species in cultures from sites that are normally sterile. The isolation of *Candida* species from nonsterile sites, such as endotracheal tube secretions or the skin or mucous membranes, is an indication of colonization, and does not establish the diagnosis of disseminated infection. In contrast to adults, in whom the diagnosis of disseminated candidiasis is documented by blood culture in only one third of cases, 80% or more of neonates with invasive candidiasis have documented fungemia.[6] The use of special media for the isolation of fungi is not required. *Candida* species grow robustly in the routine blood culture media used in most clinical laboratories, and these media usually yield the organism within 48 to 72 hours of incubation.[44]

If catheter-associated candidemia is suspected, a blood culture obtained through the catheter and one obtained peripherally should be collected before catheter removal and the initiation of therapy. The peripheral culture should be repeated to document that fungemia has resolved with catheter removal.

If disseminated candidiasis is suspected, or if a positive peripheral blood culture is obtained, blood cultures should be repeated at intervals until sterility is documented. Urine culture should be obtained by suprapubic tap or catheter. The CSF should be evaluated. CSF evaluation usually reveals a modest pleocytosis, with several hundred cells or fewer, lymphocyte predominance, and mildly elevated protein. The inflammatory response in CSF can be minimal, and one half of infants with *Candida* meningitis can have normal CSF parameters.[9] Routine cultures yield yeast within 2 to 3 days.[34] Infants with disseminated candidiasis require a baseline abdominal ultrasound examination; ophthalmologic examination; and, if central venous access catheters have been in place, echocardiographic examination of the heart and the great vessels. Subsequent examinations can be conducted if there is evidence of focal infection of these organ systems, or if the clinical status indicates. Additional laboratory tests include a baseline complete blood count (CBC), blood urea nitrogen, creatinine, potassium, and liver enzymes. The CBC can reveal thrombocytopenia, and initial renal function abnormalities can be detected, particularly in infants with VLBW with disseminated candidiasis. These usually resolve as the infection is controlled.

TREATMENT

Treatment varies by the location and extent of infection and the age of the patient. Thrush usually responds to nystatin (Mycostatin) suspension (1 to 2 mL) given orally four times daily for 5 to 10 days. Nystatin cream or ointment three times daily for 7 to 10 days is usually effective for *Candida* diaper dermatitis, although secondary bacterial infection may require treatment with another topical or systemic antibiotic. Nystatin with a corticosteroid (Mycolog-II cream or ointment) can be useful in severe cases of *Candida* dermatitis. Congenital cutaneous candidiasis requires no therapy unless the infant has evidence of pneumonia, or weighs less than 1500 g at birth, or both, at which time parenteral antifungal therapy is indicated.[42]

Amphotericin B is the mainstay of treatment for systemic candidiasis in a newborn infant (Table 39-25). It is extremely well tolerated by infants with VLBW. Pharmacokinetic studies in neonates suggest that a single daily infusion administered over 4 hours is necessary to achieve detectable serum concentrations.[1] An initial dose of 0.5 mg/kg, administered over 1 to 2 hours, can be advanced to the 1 mg/kg per day dose after 12 to 24 hours. The duration of therapy varies, but a typical course for disseminated candidiasis is a 20 to 25 mg/kg cumulative dose. For catheter-associated candidiasis, the usual course of therapy is a cumulative dose of 10 to 15 mg/kg. This duration usually is required to ascertain that the sequential blood cultures obtained after catheter removal are sterile. Infants who have a delay in removal of central catheters are at higher risk of death and neurodevelopmental delay compared with infants whose catheters are removed promptly.[3]

Amphotericin B rarely causes nephrotoxicity in infants. Initially abnormal renal function usually improves as treatment is initiated, suggesting that renal dysfunction was caused by the fungemia, rather than precipitated by the treatment. Infants receiving the initial dose of amphotericin B should be monitored for cardiac arrhythmias, but this is a rare side effect. Because amphotericin B causes renal tubular wasting of potassium, the potassium should initially be monitored daily and supplemented as required to maintain the concentration at greater than 3 mEq/dL. If daily potassium, blood urea nitrogen, and creatinine levels are stable after the first week of therapy, these can be monitored twice weekly, and the CBC and liver enzymes can be determined weekly, for the duration of the treatment course.

The combination of flucytosine and amphotericin B has been used successfully to treat systemic candidiasis, especially when the meninges are involved. Flucytosine should not be used as monotherapy because resistance can develop. The dosage range is 50 to 150 mg/kg daily, given orally in divided doses every 6 hours. Bone marrow suppression, hepatotoxicity, and gastrointestinal symptoms associated with flucytosine administration are more common when serum concentrations exceed 70 to 100 μg/mL. The CBC and liver enzymes should be monitored, and serum concentrations of flucytosine should be measured.

Available data suggest that liposomal amphotericin B and amphotericin B lipid complex are safe and effective when used as initial therapy[18,27] or for therapy in neonates with systemic candidiasis who were intolerant of or refractory to conventional antifungal therapy.[49] Pharmacokinetic studies

TABLE 39–25 Antifungal Agents Used for Treatment of Systemic Infections in Neonates

Drug	Dosage[*] (mg/kg/d)	Interval/Route	Toxicity	Comments
Amphotericin B	1[†]	q24h IV	Anemia, hypokalemia	Monitor blood urea nitrogen, creatinine nephrotoxicity, and K^+ daily initially and twice weekly if stable after 1 wk; hold dose until K^+ <3 mEq/dL is corrected
Lipid formulations	3-7[‡]	q24h IV	Less nephrotoxic than amphotericin B	Monitor renal function and K^+ as above for amphotericin B
Flucytosine	50-150	Divided q6h PO	Bone marrow suppression, hepatotoxicity, and gastrointestinal symptoms	Good penetration into CSF; must reduce dosage in patients with renal failure; monitor serum concentrations
Fluconazole	3-6	q24h PO, IV	Adjustment of dosage needed for renal impairment	Good penetration into CSF Limited experience
Itraconazole	5[‡]	q24h PO	Occasional hepatotoxicity	Limited experience
Caspofungin	1-2[‡]	q24h IV	Hepatotoxicity	Limited experience

[*] See text for details.

[†] Initial dose of 0.5 mg/kg should be followed 12-24 h later by 1 mg/kg dose administered daily. Dose should be increased to 1.5 mg/kg/d for neonates with invasive aspergillosis.

[‡] Optimal dose has not been established.

CSF, cerebrospinal fluid.

have not been performed in neonates, and randomized trials are lacking to establish the optimal and cumulative dosages, and whether these preparations should be used in combination with other antifungal agents.[43] Nephrotoxicity is less often observed with lipid formulations than with amphotericin deoxycholate. Lipid formulations have poor penetration of the kidney, however, and therapeutic failure has occurred in neonates with renal or systemic candidiasis. Until comparative data are available, the use of these products should be reserved for infants with dose-limiting toxicity attributable to conventional amphotericin B for whom renal fungal involvement has been excluded.

Among the echinocandin antifungal agents, limited clinical experience with caspofungin suggests that it is an effective, safe, and well-tolerated alternative agent to amphotericin B for neonates who have persistent fungemia, and are unresponsive to or are intolerant of amphotericin B deoxycholate. A dose of 1 mg/kg per day throughout the course of treatment and initial dosing with 1 mg/kg per day advanced to 2 mg/kg per day have been employed.[35,36] Potential toxicity in association with a daily dose of 6 mg/kg per day has been noted.[46] Early experience with micafungin revealed linear plasma pharmacokinetics over a broad dose range in experimental neonatal candidiasis, and indicated that a dose exceeding 2 mg/kg would be required to penetrate most compartments of the central nervous system.[15] Doses of 2 to 3 mg/kg have been well tolerated in premature infants.[14,37]

The efficacy and safety of fluconazole for the treatment of *Candida* fungemia have been studied in a few neonates. Treatment of infants with VLBW who had documented *C. albicans* infection has been carried out with fluconazole for 6 to 48 days.[16] An 80% cure rate was achieved, but four infants relapsed despite at least 14 days of therapy. Similarly, itraconazole has been used in a few cases, with a generally good outcome. Until an efficacy trial is available that compares amphotericin B with fluconazole or itraconazole in a direct comparison, however, amphotericin B should remain the standard treatment for neonatal candidiasis.

PREVENTION

In 2001, administration of fluconazole during the first 6 weeks of life was shown to be an effective intervention to prevent fungal colonization and invasive candidiasis in infants with birthweights of less than 1000 g.[20] Fluconazole was administered intravenously at a dose of 3 mg/kg every third day for the first 2 weeks, every other day during weeks 3 and 4, and daily during weeks 5 and 6. The efficacy and safety of fluconazole prophylaxis in preventing invasive *Candida* infections in infants weighing less than 1000 g have subsequently been shown in additional multicenter, randomized trials, which, taken together, also show a significant decrease in invasive *Candida* infection-related mortality.[23,29] Longitudinal analysis during 4 years found continued benefit without the development of fluconazole-resistant *Candida* species.[13] This evidence base supports the use of fluconazole prophylaxis in high-risk infants weighing less than 1000 g at birth, and suggests that each neonatal intensive care unit should determine its incidence of infection and institute prevention in preterm infants at high risk for infection.[21]

Coccidioidomycosis

INCIDENCE

Coccidioidomycosis is endemic in the San Joaquin Valley in California and in other areas of the southwestern United States, Mexico, Argentina, Venezuela, and Paraguay. Most susceptible individuals living in endemic areas acquire asymptomatic infection within 5 years. Disease can occur in any geographic location after reactivation of infection. Despite the high incidence of infection in endemic areas, perinatal coccidioidomycosis rarely occurs.

MICROBIOLOGY

Coccidioides immitis, the causative agent of coccidioidomycosis, is a biphasic fungus. Highly contagious mycelia grow on culture media and soil, whereas the less infectious spherules grow in tissues. The spherule contains hundreds of endospores that, when released, can become spherules.

PATHOGENESIS

The infectious arthrospores can become airborne, or can be transferred from inanimate objects contaminated with dust. Infection is acquired from inhalation of arthrospores and less commonly from direct inoculation into cutaneous lacerations or abrasions. The incubation period is 7 to 21 days. Infection occurring in infants younger than 1 week of age has been described, suggesting vertical transmission.[4] Despite several reports of disseminated infection during pregnancy, placental and perinatal infections are rare.[7,26]

After arthrospore inhalation, mature spherules develop within several days. Granuloma formation with tracheobronchial lymph node involvement can follow. In extensive disease, polymorphonuclear leukocytes infiltrate the lung, similar to the process seen with bacterial pneumonia. Hematogenous dissemination occurs frequently in infants.

CLINICAL MANIFESTATIONS

In contrast to older children and adults, whose primary infection is often asymptomatic, pneumonia is usually present in most infants with recognized infection. Chest radiographs can show focal consolidation or diffuse nodular infiltrates, hilar adenopathy, and pleural effusions. Fever, anorexia, and respiratory distress often accompany neonatal coccidioidomycosis. If the disease becomes disseminated, lesions can develop in the skin, bone, lymph nodes, liver, spleen, and meninges.

DIAGNOSIS

Clinical and radiographic features of coccidioidomycosis can resemble features seen with histoplasmosis, pulmonary tuberculosis, and viral pneumonitis. If meningitis develops, an elevated protein concentration and hypoglycorrhachia can be seen on CSF examination. Early in the course, a neutrophilic pleocytosis can be seen, but this quickly progresses to a lymphocytic predominance.

The diagnosis is best established using serologic and histologic methods. An IgM response is usually detectable 1 to 3 weeks after the onset of symptoms. A high IgG titer indicates severe disease, and decreasing titers suggest improvement. Transplacental passage of complement-fixing antibody occurs, so an increase in the infant's titer must be shown to document neonatal infection. Antibodies are detectable in CSF in patients with meningitis. Spherules occasionally can be observed on silver-stained tissue samples. Culture of the organism is feasible, but is potentially hazardous to laboratory personnel. Coccidioidin skin tests are not helpful in the neonatal period, and these skin tests are not currently available in the United States.

TREATMENT

In older children and adults, primary infection is often self-limited and requires no therapy. The frequency of disseminated disease in young infants and the high case-fatality rate warrant treatment of all neonatal infections, however. Amphotericin B is the drug of choice for the initial treatment of infection (see Table 39-25). The duration of therapy is prolonged, and anecdotal therapy suggests that fluconazole administered orally can be given to complete the course of treatment.[7,26]

Cryptococcosis

INCIDENCE

Cryptococcosis occurs worldwide. Many infections are likely to be asymptomatic, and most symptomatic infections occur in individuals older than 30 years. Infection can occur in otherwise healthy individuals, but is more common in immunocompromised hosts, including patients with acquired immunodeficiency syndrome (AIDS), malignancies, and diabetes mellitus. Cryptococcal infection in the newborn period is an extremely rare disease.

MICROBIOLOGY

Cryptococcus neoformans is an encapsulated yeast that reproduces by budding. Its natural habitat is soil, and it has been commonly found in soil contaminated with pigeon excreta.

PATHOGENESIS AND PATHOLOGY

Cryptococcosis is acquired from inhalation of the yeast with resulting primary pulmonary infection. Ingestion or cutaneous inoculation is possible; a central venous catheter may have been the source of cryptococcemia in one neonate.[11] Case reports of disease with onset shortly after birth suggest that in utero or intrapartum transmission is possible. Otherwise, there has been no evidence of human-to-human transmission. Pulmonary infection can remain localized or can disseminate hematogenously to any organ, with the meninges most commonly affected. In adults, the infection is usually subacute or chronic, with large, solitary pulmonary nodules frequently observed. Diffuse pulmonary infiltration or miliary disease with dissemination is more common in infants.

Pathologic findings vary from minor inflammatory responses to abscess formation. Noncaseating granulomas, hepatitis, and cirrhosis of the liver are common findings. Meningitis frequently leads to obstructive hydrocephalus. Granulomas of the brain have been reported.

CLINICAL MANIFESTATIONS

Infantile cryptococcosis is a multisystemic infection. The signs and symptoms are similar to congenital infection caused by *T. pallidum, Toxoplasma,* cytomegalovirus, and rubella, and include failure to thrive, jaundice, hepatosplenomegaly, chorioretinitis, rash, and intracranial calcifications. Other symptoms suggestive of a central nervous system process, such as lethargy, irritability, vomiting, and seizures, can be observed. Respiratory symptoms are minimal, but occasionally interstitial pneumonitis can be present. Infants with meningeal involvement can show a pleocytosis ranging from

40 to 1000 leukocytes/mm^3 with a lymphocytic predominance, elevated protein, and slightly decreased glucose concentrations on CSF examination.

DIAGNOSIS

Definitive diagnosis of cryptococcosis requires isolation of the organism from body fluids or tissue specimens. Fungal cultures of CSF, blood, sputum or tracheal aspirates, material from abscess cavities, and bone marrow can yield growth of *Cryptococcus*. The presence of encapsulated, budding yeast on India ink-stained CSF or respiratory tract samples is usually indicative of cryptococcal disease. Serologic investigation includes antibody and antigen detection tests, but antigen detection is the preferred technique. Latex agglutination and enzyme immunoassay for detection of cryptococcal antigen in serum or CSF are excellent rapid diagnostic tests.

TREATMENT

In healthy adults, pulmonary cryptococcosis is usually self-limited and requires no therapy. Pulmonary disease frequently disseminates in immunocompromised patients if left untreated, however. Before the introduction of amphotericin B, cryptococcosis was almost uniformly fatal. The case-fatality rate has significantly decreased with amphotericin B therapy, but at least one third of adults fail to respond to therapy, and another one fourth have relapse after discontinuation of therapy. The combination of amphotericin B and flucytosine or fluconazole is indicated as initial therapy for patients with meningeal and other serious manifestations of cryptococcal infection. Because only six cases have been reported in neonates, only anecdotal data exist for treatment. One infant with VLBW survived cryptococcemia after receiving a 6-week course of therapy with amphotericin B.[11]

Histoplasmosis

INCIDENCE

Histoplasmosis is one of the most common pulmonary fungal infections in immunocompetent humans. It occurs worldwide in temperate climates and is endemic in the Ohio and Mississippi river valleys of the United States. In older children and adults, most infections are asymptomatic; however, in young infants, infections are often apparent and frequently disseminate. Despite the high incidence of infection in endemic areas, neonatal histoplasmosis is rare.

MICROBIOLOGY

Histoplasma capsulatum is the causative agent. It is not encapsulated, but artifacts resembling a capsule can be seen with some staining techniques. It is a thermally dimorphic fungus, growing as mycelia (mold) with microconidia and macroconidia (spores) in soil and converting to yeast form at human body temperatures. Soil is its natural habitat, and it thrives in moist soil contaminated with avian or bat excreta.

PATHOGENESIS

Inhalation of conidia is the most common mode of transmission. Other routes, such as ingestion or cutaneous inoculation, occur rarely. Human-to-human transmission, if possible, has not been well described. Several days after inhalation, the spores germinate in the alveoli, releasing yeast forms. An inflammatory response, initially neutrophilic, followed by an influx of lymphocytes and macrophages, ensues. The yeasts are phagocytosed, but not killed, and begin to proliferate within macrophages and can spread hematogenously to the liver, spleen, and other organs or to regional lymph nodes through the lymphatics. The inflammatory response can result in discrete granulomas resembling sarcoid, or caseating lesions that frequently calcify during resolution.

CLINICAL MANIFESTATIONS

The clinical spectrum of histoplasmosis in children includes asymptomatic infection, pulmonary disease that can be complicated by mediastinal lymphadenopathy and subsequent tracheobronchial obstruction, primary cutaneous infection, and disseminated infection. Asymptomatic infection occurs in most older children and adults, whereas acute disseminated infection with pulmonary disease is most common in young infants.[24] The most frequently observed signs and symptoms in disseminated disease are prolonged fever, hepatosplenomegaly, anemia, and thrombocytopenia. Because the infection can disseminate to the lymph nodes, adrenal glands, gastrointestinal tract, bone marrow, central nervous system, kidneys, heart, and bones, many other signs and symptoms can be present.

DIAGNOSIS

Fungal cultures from patients with acute, self-limited pulmonary infection rarely yield the organism, but frequently are positive from patients with disseminated disease. *Histoplasma* can be isolated from lower respiratory tract specimens, blood, bone marrow, hepatic and splenic biopsy specimens, and CSF, but growth may not be detected for 8 to 12 weeks. Lysis-centrifugation of blood samples submitted for fungal culture has increased the sensitivity and reduced the interval until cultures become positive. Demonstration of intracellular yeast forms supports the diagnosis when the clinical picture is compatible. Detection of *H. capsulatum* polysaccharide antigen in serum, urine, or bronchoalveolar lavage specimens is a rapid and specific diagnostic method. Complement fixation titers greater than 1:32 or a fourfold increase in yeast-phase or mycelial-phase titers suggests acute infection.

Chest radiographs in pulmonary histoplasmosis often are negative or reveal nodular infiltrates with mediastinal and hilar adenopathy. In disseminated disease, chest radiographs most frequently are negative, but hilar adenopathy, bronchopneumonia, or miliary nodules can be present. Pulmonary and splenic calcifications can be seen on subsequent radiographs after recovery from infection. Findings common in adult disease, including pleural effusions or cavitary formation associated with chronic pulmonary infection, are not seen in infantile disease.

TREATMENT

Primary pulmonary histoplasmosis in a healthy child usually does not require treatment. Therapy is recommended for disease in infancy because the risk of dissemination is higher, and untreated disseminated disease is almost uniformly fatal.[24] Amphotericin B is effective for initial treatment of disseminated disease and other serious infections. In patients older than neonates, itraconazole is effective, either as initial treatment or after clinical improvement has been observed.

Other Fungi

Malassezia yeasts are dimorphic, lipophilic fungi that are the causative agent of pityriasis versicolor (formerly tinea versicolor). Neonates acquire *Malassezia* through direct contact with their mothers or hospital personnel.[50] *Malassezia furfur* is the most commonly isolated of the several *Malassezia* species, and has been associated with fungemia and occasionally pneumonia in premature infants with low birthweight receiving lipid emulsion alimentation through central venous catheters.[38,48] Sporadic bloodstream infections have been described, with transmission probably by the hands of medical personnel. Because it requires high concentrations of medium-chain and long-chain fatty acids to grow, *Malassezia* cannot be cultivated on Sabouraud medium without the addition of sterile olive oil. Most infections respond to temporary cessation of lipid infusions and removal of the central venous catheter. Amphotericin B should be used for treatment until a clinical response and negative blood culture are documented.

Blastomyces dermatitidis is a dimorphic fungus endemic to the midwestern, southeastern, and Appalachian areas of the United States. Blastomycosis occurs more commonly in adults than in children and is rare in neonates. Infections can be asymptomatic, limited to the respiratory tract, or disseminated. Cutaneous and skeletal lesions are the most common extrapulmonary sites of infection. Cutaneous and genital disease have been documented during pregnancy and, if inadequately treated, can result in neonatal blastomycosis.[30] The diagnosis should be considered in infants with reticulonodular pneumonia born to mothers with chronic skin infections who live in endemic areas.

Candida diaper dermatitis is the most common superficial cutaneous fungal infection in young infants; however, tinea capitis and tinea corporis have been described.[12,47] Dermatophyte infections, caused by *Microsporum, Trichophyton,* or *Epidermophyton,* are acquired postnatally from contact with contaminated soil, infected animals, or household members. Because lesions associated with dermatophytosis can resemble the lesions seen with psoriasis, seborrhea, or impetigo, they can easily be misdiagnosed.

Invasive fungal dermatitis is an entity that is recognized increasingly with the survival of infants with VLBW. These infants have the same risk factors for invasive fungal infection as described for neonatal candidiasis. It is believed that the skin serves as the portal of entry for colonizing species. Diffuse involvement with a buff-colored crust suggests *Candida* species, but *Aspergillus* and *Trichosporon* have been seen.[41] Discrete erythematous lesions that become purple or black suggest *Curvularia* or one of the Zygomycetes.[39] The diagnosis is established by a full-thickness skin biopsy showing fungal invasion of the dermis. Treatment should be initiated with amphotericin B while awaiting the histopathologic and culture results from skin biopsy.

PROTOZOAL INFECTIONS

Malaria

INCIDENCE

Worldwide, there are 300 to 500 million cases of malaria annually and greater than 2 million deaths, most of which occur in children. Malaria remains an important cause of abortion, stillbirth, and neonatal death in many parts of the world. The 81 cases of congenital malaria reported in the United States from 1966-2005 occurred almost exclusively in infants of foreign-born women who were exposed within the year before the infant's delivery.[25]

MICROBIOLOGY

Malaria is caused by an obligate, intracellular protozoan of the genus *Plasmodium*. Congenital malaria has been recorded with each species, including *Plasmodium vivax, Plasmodium malariae, Plasmodium ovale,* and *Plasmodium falciparum*. Most congenital cases have been caused by *P. vivax* and *P. falciparum*.

PATHOLOGY AND PATHOGENESIS

Malaria is transmitted by the bite of infected female *Anopheles* mosquitoes or from transfusions (maternal-fetal, blood products, or contaminated needles) of infected blood. Anemia is the result of hemolysis. Parasites can be found in other organs of the body, including the intestinal tract, liver, spleen, lung, and brain. Because *P. falciparum* and *P. malariae* have no persistent exoerythrocytic phase, relapses do not occur. *P. vivax* and *P. ovale* are associated with relapses from dormant exoerythrocytic organisms. Transfusion-related malaria and congenital malaria have no exoerythrocytic phase.

The placenta is involved in most women who acquire malaria during pregnancy. It is unclear whether transmission to the infant is transplacental or from direct contact with maternal blood during labor or parturition. Most pregnancies resulting in congenital malaria are associated with a malaria attack during pregnancy; however, congenital infection has been described after uncomplicated asymptomatic pregnancies.

Host factors that can decrease the risk of malarial infections include abnormal hemoglobin and malaria-specific antibodies. Erythrocytes with fetal hemoglobin or hemoglobin S are less likely to become infected than erythrocytes with hemoglobin A. Women living in endemic areas are continuously exposed to malaria and develop antimalarial antibodies. Maternal antibody is believed to exhibit a protective effect for the fetus. One survey found that 7% of infants born to women evaluated at seven African sites had congenital malaria.[10]

CLINICAL MANIFESTATIONS

Most infants with congenital malaria have onset of symptoms by the eighth week of life, with an average age at onset of 10 to 28 days. Occasionally, onset has been documented at several months after birth. The most common clinical findings are fever, anemia, and splenomegaly. Approximately one third of infants have jaundice and direct or indirect hyperbilirubinemia. Hepatomegaly can be present. Nonspecific symptoms include irritability, failure to thrive, loose stools, and reluctance to feed. Congenital malaria often is complicated by bacterial illnesses in developing countries. In rare cases, malaria can be complicated by hypoglycemia; central nervous system infection; splenic rupture; renal failure; and, in *P. falciparum* infections, blackwater fever (severe hemolysis, hemoglobinuria, and renal failure). Untreated *P. falciparum* infection is associated with a high case-fatality rate.

DIAGNOSIS

Although a maternal history of a febrile illness during pregnancy can be elicited in most cases, congenital disease after an asymptomatic pregnancy in women has been reported. The diagnosis of congenital malaria should be considered in any infant presenting with fever, anemia, and hepatosplenomegaly born to a mother who at any time resided in an endemic area. The diagnosis depends on demonstration of parasites in the bloodstream. Thin and thick smears should be prepared and examined on several different occasions to maximize the possibility of parasite detection.

TREATMENT

Several types of antimalarial drugs act at different stages of the *Plasmodium* life cycle. Tissue schizonticides such as primaquine are effective against exoerythrocytic forms, whereas blood schizonticides such as chloroquine, quinine, and quinidine act only on parasites in the erythrocytic phase. Because transfusion-acquired disease, including congenital infection, does not have an exoerythrocytic phase, primaquine is not required. Chloroquine, given in an initial dose of 10 mg of chloroquine base per kilogram of body weight administered orally, followed by doses of 5 mg base/kg at 6, 24, and 48 hours after the initial dose, is frequently used. For treatment of congenital disease caused by chloroquine-resistant *P. falciparum,* quinidine gluconate or the combination of quinine administered orally and clindamycin has been suggested. Mefloquine is effective against most *P. falciparum* strains, but is not approved for use in infants. Experience with newer treatment options, such as artemisinin derivatives, in young infants is limited. Severe congenital malaria can require intensive care, and exchange transfusion can be necessary for high-grade parasitemia. Current recommendations regarding treatment of congenital malaria can be obtained from the malaria branch of the Centers for Disease Control and Prevention in Atlanta, Georgia.

Pneumocystis

INCIDENCE

Pneumocystis pneumonia occurs in patients with congenital immune defects or hematologic malignancies, or patients receiving immunosuppressive medications for organ transplantation. *Pneumocystis* is an unusual cause of pneumonia in the first year of life, but it can be observed as epidemic disease, first recognized during World War II and presumed to be related to malnutrition, and as sporadic disease associated with congenital immunodeficiency or AIDS. Some surveys suggest that rare cases can develop in healthy infants.

MICROBIOLOGY

Because of difficulties in laboratory cultivation, the taxonomy of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) is inconclusive; it has features in common with protozoan parasites and fungi. *Pneumocystis* is a unicellular organism that can be found in three forms: a thick-walled cyst, a thin-walled trophozoite, and an intracystic sporozoite. Each cyst can contain up to eight sporozoites. Organisms can be detected on tissue samples stained with Grocott-Gomori methenamine silver nitrate.

PATHOLOGY AND PATHOGENESIS

Serologic studies suggest that asymptomatic infection with *Pneumocystis* is widespread and commonly occurs in the first years of life. The organisms are believed to persist in a latent stage until impairment in host defense mechanisms permits their reactivation. Disease associated with *Pneumocystis* usually is limited to the lungs. There is now evidence that person-to-person transmission is the most likely mode of acquiring new infections. Airborne transmission from mother to infant has been proposed.[33]

Postmortem examination reveals a diffuse process, with the posterior and dependent regions of the lung most significantly affected. Microscopic examination reveals an eosinophilic, foamy, honeycombed intra-alveolar exudate composed of cysts. In epidemic infantile disease, a plasma cellular infiltrate is observed (hence the name interstitial plasma cell pneumonia), whereas in sporadic disease associated with immunodeficiency or immunosuppression, there is hyperplasia of the cells lining the alveoli and minimal cellular infiltrate with a paucity of lymphocytes.

CLINICAL MANIFESTATIONS

The clinical characteristics of sporadic *Pneumocystis* pneumonia are different from the characteristics observed in epidemic infantile disease. In sporadic cases associated with congenital or acquired immunodeficiency, there is an abrupt onset of high fever, coryza, nonproductive cough, and tachypnea. There is a quick progression to dyspnea and cyanosis. Radiographic findings most commonly reveal diffuse infiltrative disease. Concurrent infections, most commonly with cytomegalovirus, occur in more than 50% of immunocompromised infants with *Pneumocystis* pneumonia.

In epidemic infantile *Pneumocystis* pneumonia, a rare disease in developed countries, the onset is slow and insidious, with nonspecific symptoms such as anorexia, diarrhea, and restlessness.[28] Cough is not prominent initially, and fever is absent. In the subsequent weeks, infants become tachypneic, cyanotic, and dyspneic, with sternal retractions and flaring of the nasal alae. Auscultatory findings are minimal, consisting of fine, crepitant rales on deep inspiration. The chest radiograph can be negative early in the course, or can reveal a perihilar or diffuse haziness that progresses to a finely granular, interstitial pattern. Coalescent nodules can form in the periphery. Pneumothorax with interstitial and subcutaneous emphysema and pneumomediastinum can occur.

DIAGNOSIS

Typical findings on radiographic studies can suggest *P. jiroveci* pneumonia, but are not diagnostic. Demonstration of *Pneumocystis* cysts or extracystic trophozoite forms establishes the diagnosis. *P. jiroveci* can be detected in induced sputum or in tracheal or gastric aspirates, but the yield is low, and detection does not imply disease.[28] Bronchoalveolar lavage or open lung biopsy can yield the organism. Serologic tests are not useful.

TREATMENT

Trimethoprim-sulfamethoxazole is the drug of choice for treatment of *P. jiroveci* pneumonia in infants. It must be used with caution in young infants because of its potential for displacement of bilirubin from albumin-binding sites. The therapeutic dose is 15 to 20 mg/kg per day of the trimethoprim component in divided doses every 6 to 8 hours. The intravenous route of administration is preferable in infants with moderate or severe disease. Treatment is usually continued for 3 weeks. In infants who do not respond to trimethoprim-sulfamethoxazole or in whom adverse reactions develop, pentamidine isethionate, 4 mg/kg given parenterally as a single daily dose for 14 days, can be used.

Although radiographic improvement can take several weeks, clinical improvement is usually seen within 4 to 6 days after beginning therapy.[28] Local reactions at the injection site, tachycardia, hypotension, pruritus, hypoglycemia, and nephrotoxicity have been associated with pentamidine administration. Trimethoprim-sulfamethoxazole is the standard for prophylaxis against *Pneumocystis* pneumonia and has been used for that purpose in infants 2 months old and older with human immunodeficiency virus (HIV) infection.

Toxoplasmosis

INCIDENCE

Among 22,845 pregnant women analyzed by the Collaborative Perinatal Research Study in the United States, 38% had *Toxoplasma* IgG antibodies, reflecting past infection, and the incidence of acute maternal infection during pregnancy was estimated to be 1.1 per 1000 women.[45] A higher incidence is seen in women born in Cambodia or Laos.[17] In the United States, 1 to 3 infants per 1000 live births have *Toxoplasma*-specific IgM antibody. Worldwide, 3 to 8 infants per 1000 live births are infected in utero. An estimated 400 to 4000 cases of congenital toxoplasmosis occur in the United States each year.

MICROBIOLOGY

Toxoplasmosis is caused by *Toxoplasma gondii,* an obligate intracellular protozoan parasite. This ubiquitous organism exists in three forms: an oocyst excreted by infected cats that produces sporozoites, a proliferative form (trophozoite or tachyzoite), and a cyst (cystozoite) found in tissues of infected animals. *Toxoplasma* can be propagated in tissue cell cultures or by animal inoculation in research laboratories.

TRANSMISSION AND PATHOGENESIS

The cat is the only definitive host, but other mammals can be infected incidentally. Farm animals (cattle, pigs, sheep) can acquire infection after ingestion of food or water contaminated with infected cat feces that contain oocysts. Humans can acquire infection by ingestion of raw or poorly cooked meat containing the *Toxoplasma* cysts or by ingestion of food or water contaminated with oocysts. Risk factors include any exposure to cat feces, such as changing cat litter boxes, playing in sandboxes, or gardening in areas used by cats.

Congenital toxoplasmosis occurs almost exclusively as a result of primary maternal infection during pregnancy. Rarely, reactivation of infection in immunocompromised women during pregnancy can result in congenital toxoplasmosis. Most maternal infections are asymptomatic or result in mild illnesses. Fatigue and lymphadenopathy involving only a single posterior cervical node or generalized lymphadenopathy may be the only manifestation. Less commonly, acute maternal infection can manifest as an infectious mononucleosis-like syndrome with fever, nonsuppurative lymphadenopathy, headache, fatigue, sore throat, and myalgias. The general risk of transmission of acute infection from mother to fetus is estimated to be 40%; however, the actual risk and the severity of congenital infection vary with gestational age. The risk of transmission increases with increasing gestational age, but the earlier during pregnancy that fetal infection is acquired, the more severe the manifestations of congenital disease.

CLINICAL MANIFESTATIONS

The classic clinical presentation of congenital toxoplasmosis is the triad of hydrocephalus, chorioretinitis, and intracranial calcifications, but there is a wide spectrum of manifestations, and more than 75% of infected newborns are asymptomatic in early infancy. As described by McAuley and colleagues,[31] the four most common presentations include (1) a healthy-appearing term infant with subclinical infection in whom symptoms develop later in childhood, (2) a healthy-appearing term infant in whom clinical evidence of disease develops in the first few months of life, (3) an infant with generalized disease at birth, and (4) an infant with predominantly neurologic involvement at birth.

Many infants with subclinical infection who were believed to be normal at birth have evidence of infection on closer evaluation, including CSF abnormalities, such as lymphocytic pleocytosis, hypoglycorrhachia, and elevated protein concentrations. If the disease goes unrecognized and untreated, these infants can present with chorioretinitis, late-onset seizures, mental retardation, developmental delay, and hearing loss later in infancy or childhood. The second group of healthy-appearing, infected infants present with hydrocephalus and chorioretinitis in the first few months of life. Manifestations of generalized infection at birth include prematurity and intrauterine growth restriction, jaundice, hepatosplenomegaly, pneumonitis, temperature instability, lymphadenopathy, and cutaneous lesions (e.g., exfoliative dermatitis, petechiae, ecchymoses, and maculopapular lesions). Other signs of generalized infection include myocarditis; nephrotic syndrome; and gastrointestinal symptoms such as vomiting, diarrhea, or feeding difficulties. The fourth group of infected infants has predominantly neurologic disease, but can have systemic manifestations as well. Subtle neurologic deficits, obstructive hydrocephalus, or acute encephalopathy can be seen. Unilateral or bilateral macular chorioretinitis frequently occurs, and infants often have rash, hepatosplenomegaly, thrombocytopenia, granulocytopenia, and typical CSF findings. The most common manifestations of congenital toxoplasmosis during the first few months of life are compared with the manifestations of congenital rubella and cytomegalovirus infection in Figure 39-12.

DIAGNOSIS

Maternal infection occurring during gestation can lead to fetal infection. Most infants with congenital toxoplasmosis have normal results on physical examination at birth. Visual and neurologic impairment results when the infection is not diagnosed and adequately treated. Generally, all suspected maternal, fetal, and neonatal infections should have confirmatory diagnostic testing performed in an experienced reference laboratory, such as the Palo Alto Medical Foundation (550-853-4828).[5] Screening for IgG antibody in pregnancy is usually performed by indirect fluorescent antibody test or enzyme-linked immunosorbent assay and confirmed by the Sabin-Feldman dye test. Several tests are available to determine the duration of maternal infection when IgG and IgM antibodies are positive. Fetal infection is best determined using amniotic fluid polymerase chain reaction amplification of the *Toxoplasma* gene *B1*.

Infection of an infant is best established definitively by intraperitoneal inoculation of placental tissue into laboratory mice, yielding cultivation of *Toxoplasma* organisms. When this is not feasible, strong evidence for the diagnosis is provided by the presence of *Toxoplasma*-specific IgM, IgA, or IgE antibody. Infants with suspected toxoplasmosis should undergo computed tomography (CT) scanning of the brain, evaluation of CSF, and indirect ophthalmologic examination.

TREATMENT

Pyrimethamine combined with sulfadiazine and supplemented with folinic acid is recommended for treatment of symptomatic and asymptomatic congenital infection. Therapy is continued for 1 year. Consultation with appropriate specialists should be sought when treating congenital toxoplasmosis.

PROGNOSIS

McLeod and colleagues[32] published the results of the national collaborative Chicago-based treatment trial for 120 infants with congenital toxoplasmosis. The duration of follow-up was a mean of 10.5 ± 4.8 years. A normal outcome was documented for 100% of infants treated with pyrimethamine and sulfadiazine for 1 year when there was not evidence of substantial neurologic disease at birth. Cognitive, neurologic, and auditory outcomes all were normal for these children. Normal neurologic or cognitive outcomes were also observed in greater than 72% of infants who did have moderate or severe neurologic disease at birth. None had sensorineural hearing loss, and most children in each group did not develop new eye lesions. These outcomes in patients treated for 1 year were markedly better than the outcomes in earlier years for infants who were untreated and infants who received only a 1-month course of therapy.

PART 4

Perinatal Viral Infections

Jill E. Baley and Philip Toltzis

Certain viruses seem to have a predilection for the fetus and may cause abortion, stillbirth, intrauterine infection, congenital malformations, acute disease during the neonatal period, or chronic infection with subtle manifestations that may be recognized only after a prolonged period. It is important to recognize the manifestations of viral infections in the neonatal period not only to diagnose the acute infection, but also to anticipate the potential abnormal growth and development of the infant.

HERPESVIRUS FAMILY

The herpesvirus family consists of numerous closely related viruses. They all have a DNA core and are enveloped in an icosahedral (20-sided) nucleocapsid. Eight viruses in the family infect infants: herpes simplex viruses (HSV) types 1 and 2; cytomegalovirus (CMV); varicella-zoster virus (VZV); Epstein-Barr virus (EBV); and human herpesviruses (HHV) 6, 7, and 8. These viruses are also characterized by the development of latent states after the primary infection.

Herpes Simplex

Neonatal herpes simplex infections are being diagnosed with increasing frequency, at a rate of 1 in every 3200 live births per year in the United States, resulting in an estimated 1500 new cases per year. The primary source of HSV infection for neonates is acquisition of the virus during delivery, yet far more women have infected genital tract secretions than there are neonatal infections. In addition, in numerous countries, neonatal infection is less common than in the United States, despite the high prevalence of genital infections, suggesting other, unknown means of protection to the neonate.

HSV are a group of large double-stranded DNA viruses within an icosahedral nucleocapsid and a lipid envelope. There is considerable cross-reactivity between the two serotypes, HSV-1 and HSV-2. Glycoprotein G is responsible for the antigenic specificity between them, as shown by the antibody response. The seroprevalence of HSV in the United States has continued to increase for HSV-1 and HSV-2. HSV-1 is now responsible for nearly 20% of neonatal infection, probably resulting from its increased seroprevalence and its increased maternal-to-neonatal transmission during reactivation of genital infection. The virus enters via breaks in the skin and mucous membranes, then attaches to the epithelial cells and begins to replicate. The virus is transported by retrograde axonal flow from the sensory nerve endings in the dermis to the sensory ganglia, where at least some portion of the viral DNA persists for the lifetime of the individual.

Fever, ultraviolet light, stress, and many undetermined reasons may cause the virus to reactivate, at which time the virus is transported antegrade down the sensory nerve axon to the skin or mucous membrane, where it again results in either symptomatic or asymptomatic disease. Either way, the virus is infectious. Analyses of viral DNA from individuals with recurrent lesions indicate that the identical virus is virtually always responsible. Superinfection with a differing viral strain is uncommon. Infection is not seasonal, and humans are the only known carriers of the infection.

HSV infections are labeled first episode, primary infections when the individual who has neither HSV-1 nor HSV-2 antibody (indicating prior infection) acquires either HSV-1 or HSV-2 in the genital tract. A first episode, nonprimary infection occurs when an individual who already has HSV-1 antibody acquires HSV-2 genital infection or vice versa. Recurrent infections occur with reactivation of latent infections.[68]

EPIDEMIOLOGY AND TRANSMISSION

Labial and oropharyngeal infections are predominantly caused by HSV-1 and may be transmitted by respiratory droplet spread or by direct contact with infected secretions or vesicular fluid. Most HSV-1 infections occur in childhood and are usually asymptomatic, sometimes causing a gingivostomatitis or mononucleosis-like syndrome. Girls have a higher seroprevalence than boys. Black children have a 35% seroprevalence by age 5 compared with 18% in white children, and the seroprevalence remains twice as high through the teen years, but is equivalent by 60 years of age.[68]

Because genital infections are usually transmitted by direct sexual contact with HSV-2, transmission most often occurs during or after adolescence. Symptomatic and asymptomatic individuals may transmit infection. Primary genital infection may cause localized pain and burning of the labia and vaginal mucosa 2 to 7 days after contact. After a period of paresthesia, vesicles full of seropurulent fluid develop. These vesicles break down easily, forming shallow ulcers and releasing numerous infectious virus particles. There is often copious watery vaginal discharge, edema, dysuria, and bilateral pelvic and inguinal lymphadenopathy, accompanied by systemic symptoms of fever, malaise, and headache. Healing may occur several weeks later. Many primary genital infections are asymptomatic, however.

Seroprevalence rates among pregnant women have indicated that at least 30% of women have serologic evidence of infection with HSV-2, but that most of these women lack a history or symptoms of infection. Not only was this seroprevalence largely unsuspected among these pregnant women, but asymptomatic viral shedding also occurred among them at a rate (roughly 1% viral shedding at any time in pregnancy) similar to that in women with symptomatic recurrences. Seroprevalence increases dramatically as the number of sexual partners increases. Recurrence is higher among women with genital HSV-2 infection than among women with HSV-1, probably because HSV-2 is more likely than HSV-1 to establish latency in the inguinal dorsal root ganglia. When viral replication is not medically suppressed, there are a median of four HSV-2 recurrences in the first year after a primary infection. HSV-1 recurs about once a year. Finally, for 70% of all women whose infants develop HSV infection, there is no history of infection or symptoms or of intercourse with a partner who has had the infection.

About 10% of HSV-2 seronegative women have HSV-2 seropositive partners. These women may remain uninfected with HSV-2 over prolonged periods despite continued, unprotected contact with a partner who is HSV-2 seropositive.

Because the seroconversion rate is 20% per year for these women, and most genital HSV-2 infections are asymptomatic, these women are at high risk of an unsuspected, primary HSV-2 genital infection during pregnancy.[68] Seroconversion rates are similar among pregnant and nonpregnant women. It is estimated that about one third of women who asymptomatically shed HSV in labor have been recently infected, and that their infants have a 10-fold or more greater risk of being infected than the infants of mothers with recurrent disease.

Women who are seronegative for HSV-1 and HSV-2 and have HSV-1–seropositive partners may acquire HSV-1 genital infection with oral sex. Oral sex has become more popular among teens because they believe it is safer sex. Overall, a woman who is seronegative for HSV-1 and HSV-2 with a discordant partner has a 3.7% chance of acquiring infection with either virus during pregnancy, and a woman who is seropositive for HSV-1 and seronegative for HSV-2 with an HSV-2–seropositive partner acquires HSV-2 infection in 1.7% of pregnancies.[68]

Transmission from mother to infant may occur via many different routes, including transplacental, intrapartum, and postnatal acquisition. Transplacental transmission (5%), responsible for in utero infection, is inferred by the documentation of HSV skin lesions and viremia at birth and by elevated specific cord IgM levels. Primary and recurrent maternal infections have been associated with congenital infection.

Intrapartum transmission is responsible for 85% of neonatal infections. The actual transmission is influenced by the type of maternal infection. A high titer of viral particles ($>10^6$/0.2 mL inoculum) is excreted for about 3 weeks with a primary maternal infection, which is more likely to involve cervical shedding than a recurrent maternal infection, in which 10^2 to 10^3 viral particles per 0.2 mL inoculum are shed for only 2 to 5 days. Maternal neutralizing antibodies may also be partially protective for a newborn in recurrent infections and may not yet be present (and available to cross the placenta) in a primary maternal infection. In a 20-year trial, 0.3% of women were found to be shedding either HSV-1 or HSV-2 asymptomatically at delivery. Neonatal disease resulted in 57% of first episode primary maternal infections (defined as having HSV-1 or HSV-2 isolated from genital secretions without having concurrent HSV antibodies), 25% of first episode nonprimary maternal infections (defined as HSV-2 isolated from genital secretions of a woman with only HSV-1 antibodies, or HSV-1 isolated from a woman with only HSV-2 antibodies), and 2% of recurrent maternal infections (present when the virus isolated from genital secretions was the same type as antibodies present in the serum at the time of labor).[20]

Because recurrent infections are so much more common, half of all neonatal HSV-2 infections occur secondary to recurrent maternal infection, even though transmission from mother to infant occurs in only 2% of the cases. The amount of neutralizing antibody also affects the severity of neonatal disease. Infants who do not receive much transplacental transfer of antibody are more likely to develop disseminated disease. Prolonged rupture of membranes ($>$4 to 6 hours) also increases the risk of viral transmission, presumably from ascending infection. Delivery via cesarean section, preferably before rupture of membranes, but at least before 4 to 6 hours of rupture, can reduce the risk sevenfold.[20]

Neonatal infection does still occur, however, even with cesarean delivery. Fetal scalp electrodes may accelerate transcervical infection and breach the infant's skin barrier, also increasing risk of infection. It was shown more recently that vacuum extraction may cause scalp lacerations resulting in HSV skin lesions at the site of application. The relative risk of vacuum extraction resulting in HSV infection was nearly 7.5 times that of spontaneous vaginal or cesarean delivery. Antenatal maternal viral culture screening for HSV shedding is of no predictive value in determining who will be shedding virus at delivery.

Finally, transmission may occur postnatally (10%). Restriction enzyme DNA analysis has been used to document postnatal acquisition of HSV and its spread within a nursery by identifying infection with the same herpes strain in infants born to different mothers. The father and the mother and maternal breast lesions have been implicated in neonatal infections. There is also concern regarding symptomatic and asymptomatic shedding among hospital personnel, one third of whom may have a history of HSV-1 lesions, and 1% of whom still have recurrent labial lesions. Individuals with a herpetic whitlow should be removed from the nursery. Removal of health care workers with other lesions would pose significant risk to neonates because it would cause significant disruption of care. Orolabial lesions should be covered with a mask, and skin lesions should be covered with clothing or a bandage. Workers should be counseled on good hand hygiene and not to touch a lesion.

CONGENITAL HERPES SIMPLEX VIRUS INFECTION

Congenital infection was found in 5% of the infants in the National Institute of Allergy and Infectious Disease (NIAID) Collaborative Antiviral Study Cohort.[159] These infants with growth restriction characteristically have skin lesions, vesicles and scarring, neurologic damage (intracranial calcifications, microcephaly, hypertonicity, and seizures), and eye involvement (microphthalmia, cataracts, chorioretinitis, blindness, and retinal dysplasia). Congenital infections are described throughout pregnancy and after primary and recurrent infections, but are most likely with a primary infection, or if the mother has disseminated infection and is in the first 20 weeks of pregnancy. Most cases are due to HSV-2. The manifestations probably result from destruction of normally formed organs, rather than defects in organogenesis, because the lesions are similar to lesions of neonatal herpes. A few children, usually in association with prolonged rupture of membranes, have isolated skin lesions that may be more amenable to antiviral therapy.

NEONATAL HERPES SIMPLEX VIRUS INFECTION

Although asymptomatic HSV infections are common in adults, they are exceedingly rare in neonates. Of all neonatal infections, 20% are caused by HSV-1 rather than HSV-2. Half of the infants are born prematurely, usually between 30 and 37 weeks of gestation, and many have complications of prematurity, particularly respiratory distress syndrome. Two thirds of the term newborns have a normal neonatal course and are discharged before the onset of disease. They may also have simultaneous bacterial infections. One fourth of the infants present on the first day of life, and two thirds present by the end of the first week.

Clinically, neonatal infections are classified as (1) disseminated, involving multiple organs, with or without central nervous system (CNS) involvement; (2) encephalitis, with or without skin, eye, or mouth involvement; and (3) localized to the skin, eyes, or mouth. Approximately 25% of cases are disseminated; 30% have CNS involvement; and 45% are localized to the skin, eyes, or mouth.

Among the 202 infants with HSV infections followed in the NIAID Collaborative Antiviral Study Group, mortality was significantly greater with disseminated infection (57%) than with encephalitis (15%), and did not occur with disease limited to the skin, eyes, or mouth.[159] The relative risk of death was 5.2 for infants in or near coma at onset of treatment, 3.8 for disseminated intravascular coagulopathy, and 3.7 for prematurity.[158] Among infants with disseminated disease, the infants with pneumonitis had a greater mortality. Sequelae among survivors were more common with encephalitis or disseminated infection, particularly with HSV-2 infection, or in the presence of seizures, but also were more likely in infants with skin, eye, or mouth infection who had three or more recurrences of vesicles within 6 months.[158] Sequelae were found in 75% of survivors with HSV-2, and only 27% of survivors with HSV-1 infection, which may be related to the in vitro susceptibility of HSV-1 to acyclovir.[160]

Disseminated Infection

Infants with disseminated infections have the worst prognosis. Disseminated infections may involve virtually every organ system, but predominantly involve the liver, adrenal glands, and lungs. Infants usually present by 10 to 12 days of life with signs of bacterial sepsis or shock, but often have unrecognized symptoms several days earlier. Although the presence of cutaneous vesicles is helpful in diagnosis, 20% of infants never develop vesicles. Disseminated intravascular coagulation with decreased platelets and with petechiae and purpura are common, and bleeding often occurs in the gastrointestinal tract. Pneumatosis intestinalis may also be present. Hepatomegaly or hepatitis, or both, is usually present, with or without jaundice. Respiratory distress, often with pneumonitis or pleural effusion on the chest x-ray, has a poorer prognosis.

Many infants die before manifesting symptoms of CNS involvement, which is common. These infants may present with irritability, apnea, a bulging fontanelle, focal or generalized seizures, opisthotonos, posturing, or coma. Cerebrospinal fluid (CSF) may be normal or may show evidence of hemorrhage. Virus can be isolated from CSF of only one third of infants with CNS symptoms. The routine use of polymerase chain reaction (PCR) on CSF has aided considerably in recognition of disease. Death usually occurs at about 2 weeks of age, roughly 1 week from the onset of symptoms, and often involves respiratory failure, liver failure, and disseminated intravascular coagulation with shock.

Encephalitis

Encephalitis may occur as a component of disseminated disease, via blood-borne seeding of the brain, resulting in multiple lesions of cortical hemorrhagic necrosis often in association with oral, eye, or skin lesions, at 16 to 19 days of life. Brain involvement results from neuronal transmission of the virus. Regardless of the source of neurologic infection, only about 60% of infants have skin vesicles, and less than half have virus isolated from the CSF. Although the CSF is occasionally normal, it usually shows a mild pleocytosis, with a predominance of mononuclear cells, an elevated protein concentration, and a normal glucose concentration. Lethargy, poor feeding, irritability, and localized or generalized seizures may be the presenting manifestations. Nearly all electroencephalograms have nonspecific abnormalities.

In 12 infants with HSV-2 encephalitis, diffusion-weighted magnetic resonance imaging (MRI) showed extensive, often bilateral changes not visible on computed tomography (CT) or conventional MRI in 8 infants. Disease was found in the temporal lobes, cerebellum, brainstem, and deep gray nuclei. Hemorrhage and watershed distribution ischemic injury were also seen. These areas progressed to cystic changes on follow-up imaging.[152] Nearly half of untreated children die from neurologic deterioration 6 months after onset, and virtually all survivors have severe sequelae (microcephaly and blindness or cataracts).

Fever is a known symptom of HSV infection and is a common reason for an infant to be taken to the emergency department in the first month of life. The American Academy of Pediatrics (AAP) Committee on Infectious Diseases recommends considering HSV infection in neonates with fever, irritability, and abnormal CSF findings, especially in the presence of seizures. In a study of nearly 6000 infants with laboratory-confirmed viral or serious bacterial infections admitted from the emergency department, only 30% of the infants with HSV infections were febrile; 50% were fever free, and 20% were hypothermic. Of the febrile infants with CSF pleocytosis, bacterial meningitis (1.3%) was more common than HSV infection (0.3%), but not statistically so. Similarly, febrile infants with mononuclear CSF pleocytosis were not statistically more likely to have HSV infections (1.6%) than bacterial meningitis (0.8%), and 1.1% of hypothermic infants presenting with a sepsis-like syndrome had HSV infection.[22] All these infants should be considered for HSV infection when presenting in the first month of life, especially if they fail to improve on antibiotics and bacterial cultures remain negative for the first 24 to 48 hours.

Skin, Eye, and Mouth Infections

Infants with disease localized to the skin, eyes, or mouth usually present by 10 to 11 days of life. More than 90% of these infants have skin vesicles, usually over the presenting part at birth and appearing in clusters. Recurrences are common for at least 6 months. Infants at risk should be monitored for localized infections (vesicles) of the oropharynx. Either HSV-1 or HSV-2 can cause keratoconjunctivitis, chorioretinitis, microphthalmos, and retinal dysplasia, later possibly leading to cataracts. One third of these infants later develop neurologic sequelae indicative of undiagnosed neurologic involvement.

DIAGNOSIS

Isolation of virus is definitive diagnostically. Cultures of the newborn (scrapings of mucocutaneous lesions, CSF, stool, urine, nasopharynx, and conjunctivae) should be delayed to 24 to 48 hours after birth to differentiate viral replication in the newborn from transient colonization of the newborn at birth. The specimens for culture may be combined to save money because it is not important where the virus is located, but whether the virus is present, with the exception of CSF specimens, which are needed to determine CNS involvement.[68] If the culture shows cytopathic effects, typing should be done. Serologic testing is not useful in neonatal disease because transplacentally transferred maternal antibody confounds the interpretation. PCR testing has become invaluable, especially for the CSF, which has a very low recovery rate for HSV cultures. PCR can also be used to test blood, scrapings of lesions, the conjunctiva, or the nasopharynx.

THERAPY

Vidarabine was the first antiviral agent used to treat HSV that was efficacious despite the toxicity. When a low-dose acyclovir (30 mg/kg per day in three divided doses) was compared with vidarabine, the morbidity and mortality were equivalent, but the ease of acyclovir administration and decreased toxicity resulted in it readily supplanting vidarabine in use. High-dose intravenous acyclovir (60 mg/kg per day in three divided doses) was then compared with low-dose acyclovir for a longer treatment duration (21 days for disseminated or CNS disease and 14 days for disease localized to skin, eyes, or mouth). High-dose acyclovir resulted in a much improved survival rate: Infants with disseminated infection had an odds ratio of survival of 3.3, and infants with CNS disease had a similar survival. The likelihood of developmentally normal survival had an odds ratio of 6.6 compared with infants treated with the lower dose.[70,71]

Infants with an abnormal creatinine clearance need to have the acyclovir dose adjusted, and all infants need to be monitored for neutropenia. Infants with CNS disease need to have a repeat lumbar puncture at the end of the course of treatment. Treatment should be continued until the CSF is PCR negative. Infants who continue to have detectable HSV DNA in the CSF by PCR at the end of therapy are more likely to die or have moderate to severe impairment. Poor prognostic indicators are lethargy and severe hepatitis in disseminated disease, and prematurity and seizures in CNS disease.[70,71]

Mortality has been tremendously decreased with high-dose acyclovir and is now 29% for disseminated disease; 4% for CNS disease; and 0% for skin, eye, or mouth disease.[70,71] Although the percentage of survivors with normal development (31%) has not changed for CNS disease, normal development among survivors of disseminated disease is now 83%, and for skin, eye, or mouth disease is greater than 98% (Figs. 39-13 and 39-14).[70,71] Neonates with skin, eye, or mouth disease with neurodevelopmental abnormalities on follow-up may represent undetected CNS disease, adverse effects of inflammation secondary to disease, or seeding from recurrent skin lesions.

To improve outcome, earlier recognition and treatment of infection is needed. Initiation of therapy in the high-dose acyclovir trial usually began 4 to 5 days after onset of symptoms, which is no better than occurred in the low-dose trial.[70] Topical ophthalmic antiviral drugs should be given to infants with ocular involvement in addition to parenteral therapy. This may include 1% trifluridine, 0.1% iododeoxyuridine, or 3% vidarabine. All other therapy is supportive.

Oral prophylactic acyclovir therapy after completion of treatment has been used to suppress recurrence in infants with skin, eye, and mouth disease.[67] There is a significant reduction in the recurrence of skin lesions, but it is unclear if this is safe, or if it would prevent neurologic disease. A trial is currently under way.[17,128]

In the United States, increased demand for parenteral acyclovir resulted in a national shortage. The U.S. Food and Drug Administration (FDA) and AAP allowed the Canadian affiliate of APP Pharmaceutical to supply its acyclovir product to the

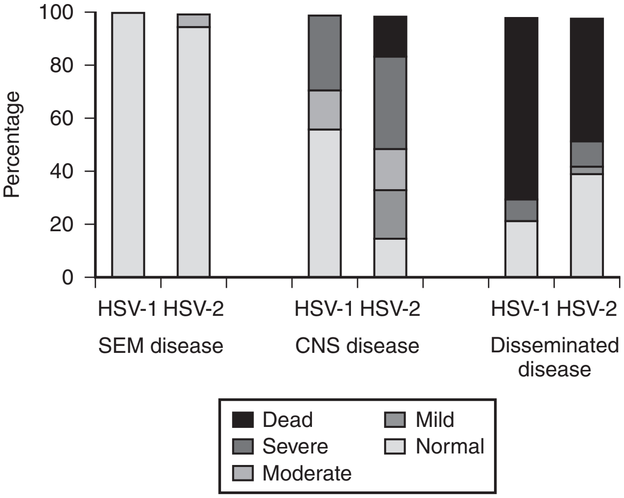

Figure 39–14. Morbidity and mortality among patients after 12 months of age by viral type, 1981-1997. CNS, central nervous system; HSV, herpes simplex virus; SEM, skin, eyes, or mouth. (*From* Kimberlin DW *et al: Safety and efficacy of high-dose intravenous acyclovir in the management of neonatal herpes simplex virus infections,* Pediatrics *108:223, 2001.)*

United States during the shortage because the product differs only in labeling. Intravenous acyclovir remains the drug of choice for neonatal HSV disease and HSV encephalitis, whereas oral acyclovir is the first choice for skin recurrences after HSV disease. If parenteral acyclovir is unavailable, intravenous ganciclovir may be used as a second-line therapy and intravenous foscarnet as a third-line of therapy for neonatal HSV disease or HSV encephalitis. Skin recurrences may be treated with oral valacyclovir.

None of these drugs have been evaluated in controlled trials in neonates for these conditions. Ganciclovir and foscarnet toxicity is significantly greater than with acyclovir and include myelosuppression for ganciclovir and metabolic derangements (hypocalcemia and hypercalcemia, hypophosphatemia and hyperphosphatemia), and possibly irreversible nephrotoxicity for foscarnet.[66] Oral valacyclovir hydrochloride is a prodrug of acyclovir. It is rapidly absorbed via the gastrointestinal tract and converted to acyclovir, reaching higher plasma levels than acyclovir used alone.

PREVENTION

In 1999, the American College of Obstetrics and Gynecology recommended that cesarean delivery be performed if a mother had HSV genital lesions or prodromal symptoms at the time of delivery. Seventy percent of mothers of infants with neonatal disease do not have a history or symptoms of HSV infection, however, and their partners do not have a history of HSV infection, and neonatal infection may still occur even if a cesarean delivery is performed. Repetitive cervical cultures do not predict whether a mother will be shedding virus at delivery. Mothers should be counseled regarding the signs and symptoms of disease, and some may then recognize infection. If rupture of membranes has been present longer than 6 hours, some experts still recommend cesarean delivery in the face of genital lesions, but data are lacking, and controversy exists. Scalp electrodes should be avoided. There is also no consensus for treatment with ruptured membranes in a mother with lesions but a very immature fetus.

If an infant is delivered vaginally to a mother with recurrent genital lesions (5% risk of infection), most experts do not recommend treating the infant. Cultures and PCR of the neonate should be obtained at 24 hours of life, and the infant should be observed carefully. Circumcision should be delayed until cultures are known to be negative. Hand washing should be emphasized. Breast feeding may be allowed if there are no lesions on the breast. The mother needs to be taught the signs and symptoms of neonatal disease because the cultures do not always detect neonatal disease.

Whenever a mother has active genital lesions at the time of the birth of the baby, and she has no history of prior herpetic infection, both a herpes culture and PCR need to be sent, regardless of whether the birth is via Cesarean section or vaginal. Type-specific serology can be used to determine if this is a recurrent infection or if it is a first episode infection. Since the risk of infection to the newborn is greater than 50% in a primary, first-episode infection and 25% in a non-primary, first-episode infection in the mother, these infants should have surface cultures and blood and surface PCR for HSV, serum ALT and CSF cell count, chemistries, and PCR for HSV sent at 24 hours of life, earlier if the baby is ill or premature or had prolonged rupture of membranes. Acyclovir should be started after the evaluation. If it is a recurrent infection, the acyclovir may be discontinued after a negative evaluation. Empiric acyclovir treatment should be considered for 10 days for any first-episode infection, whether primary or non-primary, even if the baby's evaluation is negative. If a CSF infection is suspected, treatment should be continued for 21 days, after which a repeat CSF PCR needs to be sent. Another seven days of acyclovir should be given whenever the PCR is positive for HSV.

There is also considerable controversy concerning the prevention of a primary HSV genital infection in a seronegative pregnant woman. Although some authorities advocate for type-specific serologic screening for HSV in all pregnant women, arguing that many mothers want the information, that they may be counseled against oral or unprotected sex, and that strategies may be devised from the data that are collected, others argue against testing, stating that it is not cost-effective, there is no recommended intervention, and the unexpected positive test can cause significant psychological and social distress. Targeting women for testing who are at high risk for infection misses too many seronegative women. Some treatment strategies do exist, however. It has been shown that the use of condoms in at least 70% of sexual intercourse between a woman seronegative for HSV and a man seropositive for HSV reduced transmission by more than 60%.[68] Antiviral suppression with valacyclovir for 8 months in seropositive male partners reduced the transmission of HSV-2 infection to pregnant women by 48% and symptomatic infection by 75%.[28]

Many obstetricians now routinely recommend antiviral prophylaxis (valacyclovir or acyclovir usually) in the last trimester of pregnancy to suppress viral recurrences. Although no major malformations have been associated to date with the use of acyclovir in pregnancy, the safety to the fetus has not been determined. In a Cochrane Database meta-analysis of third-trimester antiviral prophylaxis, women were less likely to have a recurrence at delivery (relative risk 0.28), a cesarean delivery for genital lesions (relative risk 0.30), and HSV detected at delivery (relative risk 0.14).[55] Although there were no cases of neonatal disease among the infants, there were too few patients to draw a conclusion about neonatal risk. Neonatal infection may occur because viral shedding does still occur. There has been some success in vaccine development for women who are seronegative for HSV-1 and HSV-2, but the trials still need to be performed.

Cytomegalovirus

The cytomegaloviruses are the largest viruses in the herpesvirus family and are noted for their worldwide distribution among humans and animals. The virus is highly species specific, and humans are the only known reservoir for disease among humans. After primary infection, the virus enters a latent state, from which reactivation may frequently occur. Reinfection may also result from any of the thousands of human strains, which are homologous, but not identical. The differing antigenic makeup of the various strains may make it possible to identify the source of the viral infection.

The virus has a double-stranded DNA core surrounded by an icosahedral, or 20-sided, capsid. This capsid is surrounded by amorphous material, which is surrounded by a lipid envelope, probably acquired during budding through the nuclear membrane. The virus is named for the intranuclear and paranuclear inclusions seen with symptomatic disease—cytomegalic inclusion disease. These inclusion bodies often yield an "owl's eye" appearance to the cells. The virus does not code its own thymidine kinase or DNA polymerase, which is important when considering treatment. The virus is cultured in the laboratory only in human fibroblasts, although it replicates in vivo primarily in epithelial cells.

EPIDEMIOLOGY AND TRANSMISSION

CMV is currently the most common intrauterine infection. CMV is responsible for congenital infection in 0.15% to 2% of newborns, and it is a leading cause of deafness and learning disability. Infection is more prevalent in underdeveloped countries and among lower socioeconomic groups in developed countries, where crowding and poor hygiene are more common. Each year, 2% of middle to high socioeconomic class women of childbearing age seroconverts compared with 6% of women from lower socioeconomic groups. Seropositivity also increases with age, breast feeding for more than 6 months, nonwhite race, number of sexual contacts, and parity.

Transmission of CMV requires close contact with contaminated secretions because the virus is not very contagious. The virus can be cultured from urine, cervical secretions, saliva, semen, breast milk, blood, and transplanted organs, and all these sites intermittently excrete virus. Viral excretion is particularly prolonged after primary infection, but also occurs with reactivation of infection. Congenitally infected infants may shed virus for years and serve as a large reservoir for spreading infection to others. Toddlers also may shed the virus for prolonged periods compared with adults, in whom the humoral and cellular defense mechanisms lead to a latent state within a few months.

Transplacental transmission is responsible for congenital infection in 1% of newborns, and intrauterine fetal death may be more likely. Congenital infection may occur after either a primary or a reactivated infection in the mother. Overall, only 5% to 10% of congenital infections are symptomatic, and these are more likely after a primary maternal infection, although symptomatic infections have been reported in women with reactivation infections. Data implicate reinfection as the cause of some of these symptomatic infections. Symptomatic infants have a mortality of 20% to 30%, and two thirds of survivors may have sequelae. The 90% of infants with asymptomatic infection at birth also have a 5% to 15% risk of later sequelae, however.

Even with primary maternal CMV infection during pregnancy, transplacental infection occurs in only 30% to 40% of the fetuses, and only 10% to 15% of these infected fetuses develop symptomatic disease. With recurrent maternal CMV infection during gestation, only 1% to 3% of fetuses are infected. Although transmission seems to be increased in the third trimester, the risk of malformations (which occur during the period of organogenesis) lessens. The fetus may be infected throughout gestation. Infection seems to be more significant in the first half of pregnancy when the virus has considerable teratogenic potential. Neurons migrate from the periventricular germinal matrix to the cortex between 12 and 24 weeks of gestation. This process may be interrupted by infection, resulting in CNS malformations. In the second half of pregnancy, during the period of myelination, white matter lesions may develop, as seen on MRI.[87]

Perinatal infection is responsible currently for an additional 3% to 5% of infections among newborns, resulting from exposure to cervical secretions and blood during delivery or via breast milk. Transmission in early childhood may occur from child to child and from child to other family members. There is also an implication that infection may occur via fomites because virus may survive in urine for hours on plastic surfaces and has been cultured from toys in daycare centers. Nearly half of mothers of premature infants infected in the nursery seroconvert within 1 year and the same proportion of susceptible family members seroconvert when a single family member is infected.

Daycare compounds the problem. There is a 15% rate of infection among parents of children in daycare, particularly if the child is younger than 18 months. Mothers of children in daycare, particularly if they are of middle socioeconomic status and previously seronegative, are at significant risk of developing a primary CMV infection in a subsequent pregnancy; this may account for 25% of symptomatic congenital infections. Seronegative women who work at daycare centers have an 11% seroconversion rate per year, well above any predictable rate, and are at considerable occupational risk.

Similar concern has been expressed about women health care workers and their occupational risk. Although these women are exposed to virus, the data do not support an increased risk of transmission of the virus.

After early childhood, viral transmission seems to be minimal until puberty, when sexual activity begins. Infection rates are highest among adults with multiple sexual partners. An additional risk of infection occurs with blood transfusions and organ transplants to seronegative individuals. Transmission may be prevented by requiring all blood products to come from seronegative donors. Alternatively, the white blood cells carrying the virus may be removed by using frozen, deglycerolized red blood cell transfusions or by using filters to remove the leukocytes. Neither the transfusion method nor using filters completely protects against transmission of virus, however.

CMV transmission via human breast milk feeding has been reported to result in infection in premature infants (<32 weeks' gestation), resulting in a sepsis-like infection. Freeze-thawing of milk does not prevent transmission. Long-term outcome has not yet been determined, but in a report of 40 preterm infants who developed viruria in the nursery, most likely from breast milk feedings, neonatal outcome was not different from that of control infants. The infants exhibited cholestasis, elevation of C-reactive protein, mild neutropenia, and thrombocytopenia, but these symptoms resolved.[102]

MATERNAL CLINICAL MANIFESTATIONS

Most women are asymptomatic during either primary or recurrent infection, and pregnancy does not alter the clinical picture. A mononucleosis-like illness, which is heterophil negative, may develop in 5% to 10% of women. Other manifestations are rare.

ASYMPTOMATIC CONGENITAL INFECTION

Although 85% to 90% of all infants with congenital CMV are asymptomatic at birth, 15% may be at risk for later sequelae. The results of follow-up of 330 infants with asymptomatic infection who were mostly of low socioeconomic status are shown in Table 39-26. The most important sequela seems to be sensorineural hearing loss, which is often bilateral and may be moderate to profound. The presence of periventricular radiolucencies or calcifications on CT is highly correlated with hearing loss. The hearing loss may be present at birth or may appear only after the first year of life, and is frequently progressive, owing to continued growth of the virus in the inner ear. There is a very low risk of chorioretinitis; it may not be present at birth, but may develop later secondary to continued growth of the virus. A further finding may be a defect of tooth enamel in the primary dentition, leading to increased caries. Neurologic handicap may occur, but is uncommon. Premature infants are most at risk.

SYMPTOMATIC CONGENITAL INFECTION

Cytomegalic inclusion disease occurs in only 10% to 15% of infected infants and results in multiorgan involvement, particularly of the reticuloendothelial system and CNS. Death may occur at birth or months later, resulting in an overall mortality of 20% to 30%, usually from disseminated intravascular coagulation, bleeding, hepatic failure, or bacterial infection.

CNS involvement may be diffuse. Infants may be microcephalic, have poor feeding and lethargy, and have hypertonia or hypotonia. They may also exhibit intracranial calcifications of the basal ganglia and cortical and subcortical regions, ventricular enlargement, cortical atrophy, or periventricular leukomalacia. Most commonly, an infant who is small for gestational age or premature has hepatosplenomegaly and abnormal liver function tests. Hyperbilirubinemia, which occurs in more than half of infants, may be transient, but is more likely to be persistent, with a gradual increase in the direct component. Petechiae, purpura, and thrombocytopenia (direct suppression of megakaryocytes in the bone marrow) usually develop after birth and may persist for weeks. Approximately one third of infants with congenital infection are thrombocytopenic, and one third of those have severe thrombocytopenia, with platelet counts less than 10,000/dL. There may also be a Coombs-negative hemolytic anemia. Diffuse interstitial or peribronchial pneumonitis is possible, but less common than with perinatally acquired disease. Table 39-27 lists the clinical findings in 24 newborns with symptomatic CMV infection.

TABLE 39–26 Sequelae in Children after Congenital Cytomegalovirus Infection

Sequelae	Symptomatic Infection (%)	Asymptomatic Infection (%)
Sensorineural hearing loss	58	7.4
Bilateral hearing loss	37	2.7
Speech threshold, moderate to profound	27	1.7
Chorioretinitis	20.4	2.5
IQ <70	55	3.7
Microcephaly, seizures, or paresis/paralysis	51.9	2.7
Microcephaly	37.5	1.8
Seizures	23.1	0.9
Paresis/paralysis	12.5	0
Death	5.8	0.3

Prognosis

Fowler and colleagues[39] showed that although maternal antibody may not prevent congenital CMV infection, it lessens the severity (Table 39-28). Sequelae were found in 25% of infants after primary infection, but in only 8% after recurrent infection. Likewise, mental impairment (IQ <70), sensorineural hearing loss, and bilateral hearing loss were found in 13%, 15%, and 8% of infants after primary maternal infection, but only 15% of infants born after recurrent maternal infection had sensorineural hearing loss, and none had mental impairment or bilateral hearing loss. These infants also showed the progressive nature of sequelae after primary and recurrent infection (Fig. 39-14).

Ramsay and colleagues[121] looked at the 4-year outcome of 65 neonates with symptomatic congenital CMV in Britain and found a better prognosis than previously reported from

the United States (Table 39-29). Overall, the rate of neurologic abnormalities was 45%. Infants who presented with abnormal neurologic findings other than microcephaly had the worst prognosis, with a 73% rate of gross motor and psychomotor abnormalities compared with a 30% rate among children who did not present with neurologic findings. A Japanese study of 33 congenitally infected infants found that abnormal fetal ultrasound abdominal findings (ascites or hepatosplenomegaly) were associated with liver dysfunction and a 53-fold increase in mortality; infants who had no abdominal findings survived.[89] Data are also accumulating that neonatal viral blood load (>1000 copies per 10^5 PMN via quantitative PCR) may also predict infants who will develop sequelae, regardless of whether the infants were symptomatic or asymptomatic after birth.[76]

PERINATAL INFECTION

Mothers with recurrent CMV infection usually transfer significant antibody to the infant in utero. Even if this antibody transfer does not occur, a term infant who acquires infection after birth, denoted a perinatal infection, is usually asymptomatic. Transmission may occur in passage through the birth canal, via breast milk, or secondary to blood transfusion. Breast-feeding infants largely seroconvert. The incubation period is 4 to 12 weeks. Term infants may develop pneumonitis secondary to CMV, and present with cough, tachypnea, congestion, wheezing, and apnea. Although the mortality rate may be 3%, few infants require hospitalization. In contrast, premature infants, often infected through blood transfusion, have a high rate of serious or fatal illness. They also may develop pneumonitis, but with a picture of overwhelming sepsis, hepatosplenomegaly, thrombocytopenia, and neutropenia. There may be an increased risk in these infants of neuromuscular handicaps, although there does not seem to be a higher rate of sensorineural hearing loss, microcephaly, or chorioretinitis.

NEUROLOGIC IMPAIRMENT

Not all infants with symptomatic disease at birth have neurologic impairment. One third of these infants may have a normal neurologic outcome; however, 5% to 15% of asymptomatic infants may have sequelae. Increasing data are correlating abnormal findings on cerebral ultrasound, CT, or MRI with long-term neurodevelopmental or neurosensory sequelae. The numbers of infants per report are small, but collectively all show this correlation.* Of symptomatic infants with abnormal CT findings, 90% had neurodevelopmental or neurosensory sequelae,[13] whereas all infants with abnormal ultrasound findings had either one or more sequelae or death; however, none of 45 infants with normal ultrasound results had long-term sequelae (Table 39-30).[6] MRI may be particularly useful in detecting white matter or gyral abnormalities.[106,148] Finally, a β_2-microglobulin concentration in the CSF also seems to indicate the severity of brain involvement in congenital disease.

HEARING AND VISUAL IMPAIRMENT

Congenital CMV is the most significant cause of sensorineural hearing loss in childhood: 10% to 15% of all infants experience loss, but hearing loss may be detected in 30% to 65% of symptomatic infants.[87] The hearing loss tends to be more severe and to occur earlier in infants with symptomatic infection. The loss can be progressive or fluctuate and may not

occur until 6 years of age. Less than half of all neurosensory hearing loss secondary to CMV is detected by newborn screening. The viral burden of the newborn, as determined by PCR of the dried blood spots on Guthrie cards or in the urine or peripheral blood, seems to correlate well with the risk of developing hearing loss and deafness, and may provide a means of determining which infants should receive antiviral therapy.[12,14,154]

Chorioretinitis may be found in 15% to 30% of symptomatic newborns. Children often have impairment or strabismus secondary to chorioretinitis, optic atrophy, or central cortical lesions and macular scarring.

ANTENATAL DIAGNOSIS

Because most women remain asymptomatic with CMV infection, screening for primary infection is necessary to determine risk. CMV IgG, which has high sensitivity and specificity, reliably diagnoses primary infection. Few European or American countries routinely screen for seroconversion, however, because there is no consensus for treatment of either a newly infected pregnant woman or her infant. Detection of CMV IgM may indicate a recent infection, but IgM also increases with reactivation of latent infection. CMV IgG avidity testing may be helpful: the binding capacity or avidity of IgG is low just after an infection and increases with time. CMV DNA may also be detected during acute infection from the peripheral blood.

If a primary maternal infection is suspected, or ultrasound shows abdominal or cerebral findings or intrauterine growth restriction, fetal diagnosis may be undertaken. Cordocentesis is unnecessary because the sensitivity is lower and the risks are greater than with amniocentesis. CMV may be detected in the amniotic fluid by viral culture or by PCR for CMV DNA with great sensitivity if the amniotic fluid is sampled at 21 to 23 weeks of gestation and at least 5 to 6 weeks after onset of maternal infection.[78] A high viral load seems to correlate with the development of a symptomatic infection and neurodevelopmental sequelae.

NEONATAL DIAGNOSIS

Virus isolation in tissue culture remains the most sensitive and specific test for diagnosis of congenital CMV in newborns. Isolation of virus from an infant within the first 2 to 3 weeks of life confirms the presence of a congenital infection. The virus is usually isolated from urine, but may be isolated from saliva, peripheral blood leukocytes, and other body fluids. Urine specimens should be refrigerated (4°C), but never frozen or stored at room temperature. The recovery rate remains at 93% in urine after 7 days of refrigeration and decreases to 50% after 1 month. Using hyperimmune sera or monoclonal antibodies, early antigens may be detected in tissue culture 24 hours after inoculation.

The diagnosis may also be made from urine, using DNA hybridization or PCR DNA amplification. A fourfold increase in IgG titers in paired sera or a strongly positive IgM anti-CMV may be used to make a presumptive diagnosis. The detection of serum IgM is complicated, however, by frequent false-positive and false-negative findings. As reported earlier, detection of CMV DNA by PCR in peripheral blood or on dried blood spots on Guthrie cards may be prognostic.

TREATMENT

In contrast to other herpesvirus infections, CMV does not induce its own thymidine kinase. Because acyclovir requires thymidine kinase, it has no efficacy in CMV. Ganciclovir has shown efficacy against acquired CMV in patients infected with human immunodeficiency virus (HIV), particularly for retinitis, but has significant toxicity (primarily reversible neutropenia and thrombocytopenia), and there is a high relapse rate after cessation of therapy. Very little is known about its safety and efficacy in neonates.

Kimberlin and coworkers[72] randomly assigned neonates with symptomatic disease to receive 6 weeks of therapy with ganciclovir versus no treatment and followed the hearing with brainstem auditory evoked response. When tested at 6 months, 84% of treated infants maintained normal hearing or improved their hearing, in contrast to 59% of control infants. None of the treated infants had worsening of hearing at 6 months compared with 41% of untreated infants. When tested at 1 year, 21% of treated infants and 68% of control infants had worsening of hearing. Neutropenia was three times more common (63%) in treated infants than in untreated infants. This study raises many questions. It is unknown whether improvement in hearing would be maintained long-term or what the impact of improved hearing is in infants with a high risk of developmental problems. Viral excretion in urine returns to pretreatment levels within 2 weeks after ganciclovir is discontinued, as does viral load. Treatment with ganciclovir can be considered for symptomatic infants, but cannot be routinely recommended.

PREVENTION

Several reports have looked at the pharmacokinetics of a commercial grade valganciclovir oral solution, but the results cannot be extrapolated to the use of currently available drug. The Collaborative Antiviral Study Group has begun a 6-week versus 6-month study of oral valganciclovir to determine if longer viral suppression is more efficacious.[2,69]

Prevention is the most important available means to avoid infection. Women childcare workers, especially when their children are younger than 2 years, need to be counseled about the risks of CMV in pregnancy and taught good hand washing procedures, as do women health care workers, particularly in nurseries. CMV is readily destroyed with soap, detergents, or antiseptics. Good hygiene, including hand washing and not kissing on the mouth, should be actively taught to all pregnant women. Transmission of CMV via blood transfusions may be largely eliminated by the use of blood from antibody-negative donors; by using leukocyte-depletion filters; or by using frozen, deglycerolized red blood cells. Vaccines are being studied for their safety and efficacy, but at present are years away from being clinically available.

When a pregnant woman has been infected with CMV, and her fetus has been diagnosed with infection, few options have existed, apart from abortion. The use of passive immunization with CMV-specific hyperimmune globulin, primarily given intravenously (a few had intra-amniotic injections), is promising. It seems to be safe. Only 1 of 31 infants whose mothers received CMV hyperimmune globulin developed symptomatic disease (37%) compared with 7 of 14 infants of untreated women (50%).[103] In a later study, three infants infected with CMV who had fetal cerebral abnormalities and whose mothers were treated with CMV hyperimmune globulin had regression of ultrasound findings and normal neurodevelopmental outcome at 4 to 7 years of age.[104]

Varicella-Zoster Virus

Varicella (chickenpox) is one of the most highly communicable human diseases. It is the result of a primary infection with VZV, which is one of the human DNA herpesviruses. After infection, latent virus persists in the dorsal root ganglia. The localized rash of herpes zoster results from a reactivation of infection, in which the virus begins to multiply within the ganglia and to propagate down the sensory nerves to its dermatomes.

EPIDEMIOLOGY AND TRANSMISSION

Humans are the only known reservoir of VZV. Immunity is lifelong and widespread. Of young adults, 70% to 80% have a history of chickenpox, and this has been found to be quite reliable. Conversely, only 10% to 20% of individuals lacking a history of chickenpox have been found to be seronegative, even though asymptomatic infection is believed to be unusual. Chickenpox may rarely occur in seropositive individuals, and this has been reported among pregnant women. Most reinfections are mild, however.

The initial protection against VZV depends on IgG. Neonates become ill because they are exposed to high titers of the virus from the mother, yet have an absence of antibody. In contrast, limitation of the severity of the infection and recovery from infection largely depend on cellular immunity, or T cells. Pregnant women are immunosuppressed with decreased T cell immunity, so disease can be very severe.

Chickenpox is seen year-round, with some increase in winter months, and is worldwide in distribution. In household contacts, 90% of susceptible individuals are infected. Transmission of the virus occurs via airborne respiratory droplet spread or via contact with the virus in the vesicular lesions of either varicella or, rarely, zoster. Although it is well documented that susceptible individuals may develop varicella after exposure to zoster lesions, varicella-zoster does not develop after exposure to chickenpox. Transmission may occur from 1 to 2 days before the onset of the rash until all vesicular lesions are dried and crusted, at least 6 days after onset of the rash. The incubation period is 10 to 21 days after exposure, unless the individual has been given varicella-zoster immune globulin, which may delay the onset of the infection for 28 days.

After replication of the virus within the nasopharynx and invasion of the local lymph nodes, there is a transient viremia, which seeds the viscera. Viral multiplication continues, causing a greater viremia and widespread cutaneous involvement. Subsequent viremias result in crops of vesicles, followed by the development of latency within the dorsal root ganglia.

CLINICAL MANIFESTATIONS

After a short prodrome of fever, headache, and malaise, there is a generalized exanthem, which begins on the face and trunk and proceeds centripetally. Recurrent crops of vesicles appear for 2 to 5 days, then crust and scab, usually healing without scarring. Secondary bacterial infection of the cutaneous lesions is the most common complication. Most other complications are rare, including encephalitis, myocarditis, arthritis, and glomerulonephritis.

Varicella pneumonia is the most common cause of mortality. The onset of fever and cough usually occurs within 2 to 4 days after the development of the rash, but may occur later. Radiographic changes consist of diffuse, nodular lesions with perihilar prominence. Dyspnea, cyanosis, rales, and chest pain may be severe, and there may be hemoptysis. Although only 15% of adults develop pneumonia, 90% of all cases of chickenpox pneumonia occur among adults. Immunocompromised individuals are also at increased risk.

VARICELLA IN PREGNANCY

There does not seem to be an increased risk of spontaneous abortion or prematurity as a result of maternal chickenpox, although prematurity and intrauterine growth restriction are common among infants with congenital varicella syndrome. Despite early reports of increased mortality, there is no evidence that chickenpox, in the absence of pneumonia, is more severe in pregnant women than among nonpregnant individuals. Mortality of 40% with chickenpox pneumonia has been reported among pregnant women who did not receive antiviral therapy. Reports of the use of intravenous acyclovir for varicella pneumonia suggest that it may improve the outcome. To date, there have been no congenital anomalies attributed to the use of acyclovir in pregnancy.

Because of the potential for increased mortality, varicella-zoster immune globulin (VZIG) may be useful for passive immunization of a susceptible pregnant woman after a significant exposure to varicella. Controlled trials are unavailable, however. VZIG needs to be administered within 96 hours of exposure and, preferably, after susceptibility has been confirmed serologically. VZIG is available only as an investigational new drug at the time of publication, and may be requested by calling 800-843-7477, a 24-hour number at FFF Enterprises. If VZIG is unavailable, immune globulin intravenous can be used. There are no controlled trials, but the VZV IgG titer can be significant, although the titers vary from preparation to preparation. If VZIG is unavailable, or more than 96 hours have passed since exposure, some infectious disease experts recommend the use of intravenous acyclovir for prophylaxis in a pregnant woman. Uncertainty continues regarding its effect on the fetus. VZIG may not protect the fetus from infection. Likewise, the absence of signs of maternal chickenpox after the use of VZIG does not indicate that the fetus is protected. Ultrasound evaluation revealing a wasted limb may assist in the diagnosis of an infected fetus, although this is, of necessity, a late diagnosis.

CONGENITAL VARICELLA SYNDROME

Maternal varicella has been shown to be teratogenic. Intrauterine infection occurs as a result of hematogenous dissemination across the placenta and can occur even with mild maternal infection.[33,111] The risk is highest (2%) in the first 13 to 20 weeks of gestation, but may occur after 20 weeks. A later maternal infection is more likely to result in less severe fetal manifestations. Before 13 weeks' gestation, the risk is only 0.4%.[48] Although portions of the congenital syndrome have been seen after maternal zoster, the full syndrome has not been seen, presumably because viremia is uncommon with zoster, and some preexisting immunity is present. Theoretically, the fetal lesions result from the development of zoster in utero. Infants born to mothers infected with varicella in pregnancy, yet who did not develop symptomatic congenital infection, have presented with zoster early in life without having been infected with varicella postnatally.

The typical features of the congenital syndrome include cicatricial cutaneous lesions with limb involvement, ocular abnormalities, and severe mental retardation. The condition usually progresses to an early death. The skin lesions usually are over an involved limb, sometimes over the contralateral limb, and are often depressed and pigmented in a dermatomal distribution. Cataracts, microphthalmia, chorioretinitis, cerebral atrophy, seizures, and mental retardation may occur; sometimes bowel and bladder dysfunction also may occur. Hypoplasia of the bone and muscle of a limb is prominent.

Maternal counseling is difficult because the incidence of the syndrome is so low as to preclude routinely recommending abortion. Maternal infection may have a 25% incidence of fetal varicella, but this does not indicate that the fetus will develop congenital varicella syndrome. Similarly, chorionic villus sampling with PCR to show virus and cordocentesis to show fetal VZV IgM indicate only fetal infection, not the development of the congenital syndrome.

The most helpful prenatal test is fetal ultrasound. Although the abnormalities do not develop immediately, most are present before 20 weeks' gestation. Limb abnormalities carry a 50% risk of mental retardation and early death. Hydrocephalus, liver calcifications, hydrops fetalis, and polyhydramnios may also be seen.

PERINATAL CHICKENPOX

Chickenpox is considered congenital when it occurs within the first 10 days of life, and it results from transplacental transmission of the virus from mother to fetus. Maternal varicella, particularly occurring from 5 days before delivery until 2 days after delivery, results in a higher neonatal mortality (20% to 30%) because there has not been enough time for maternal antibody to develop and transfer across the placenta to the fetus. The fetal attack rate is 24% to 50%. The incubation period is shorter—9 to 15 days from the onset of maternal rash to the development of fetal or neonatal disease. Infants may have a very mild infection with few lesions or may have severe disease, with widespread cutaneous and visceral involvement, including encephalitis and hepatitis. Death most often occurs secondary to pneumonia.

Zoster may also occur and represents an intrauterine infection. Dried blood spots from the Guthrie cards of more than 400 children with cerebral palsy were compared with case controls for the presence of neurotrophic viruses as determined by PCR.[42] Although seroprevalence was high even in control infants (nearly 40%), the presence of VZV DNA nearly doubled the risk of cerebral palsy.

Postnatally acquired chickenpox occurs between 10 and 28 days of life. The infection is usually mild and is unlikely to result in death. An outbreak may occur within the neonatal intensive care unit (NICU), but is much less common than in pediatric units.

LABORATORY DIAGNOSIS

Viral isolation from vesicular fluid or other tissues is definitive, but not easy to do. Demonstration of the VZV antigen can be accomplished with immunofluorescence, and PCR can be used to detect VZV DNA. Serologic testing can detect an increase in antibody titer and document infection. The presence of specific IgM usually indicates recent infection, but is an unreliable indicator.

THERAPY AND PREVENTION

The primary approach to varicella should be preventive. With the licensure of the live, attenuated varicella vaccine, it may be possible to immunize women of childbearing age actively before pregnancy. The vaccine seems to protect 85% of individuals vaccinated. Pregnancy should be avoided for at least 1 month after vaccination, but nursing mothers may be immunized. Infants should be vaccinated promptly, as per the immunization schedule, at 12 to 18 months.

VZIG should preferably be given within 96 hours of exposure. It modifies infection, but does not prevent it. Passive immunization should be administered to any infant born to a mother who develops varicella from 5 days before delivery until 2 days after delivery. Because a high dose would be needed, it is not recommended that the mother be given VZIG before the birth for passive immunization of the infant.

Acyclovir is the antiviral drug of choice for any infant with severe or potentially severe chickenpox, whether congenital or postnatal in origin. No acute toxicity has been shown after acyclovir use for neonatal HSV infections, although the dosage for neonatal chickenpox is much higher, and the long-term toxicity is unknown.

Although nosocomial cases of chickenpox are uncommon in the nursery, they may occur. Strict respiratory droplet isolation of any patients with active lesions or in the incubation period needs to be implemented, and only visitors and staff with prior immunity should be allowed in the room. Strict hand washing is a necessity. Postnatal exposure of a term infant 2 to 7 days old should carry little additional risk. Infants with low birthweight or preterm infants may be at considerable risk, however, because they were born before the transfer of maternal antibody across the placenta. All hospitalized exposed preterm infants with birthweight 1000 g or less or gestational age less than 28 weeks should receive VZIG or intravenous acyclovir, regardless of the maternal immune status. Hospitalized, exposed preterm infants who were 28 weeks' gestation or more should receive VZIG or intravenous acyclovir if the mother lacks a reliable history of chickenpox or serologic evidence of immunity. VZIG cannot be used to control the spread of varicella in a nursery because it only modifies, but does not prevent, the development of chickenpox.

Strict preventive measures are also necessary in the delivery and nursery services. If the mother has active lesions of chickenpox at delivery, she must be isolated from patients and staff. If the maternal lesions appear within 5 days before delivery and 2 days after delivery, the infant should be protected further with VZIG. If the mother had chickenpox before delivery, and her lesions have healed, she need not be isolated, but the infant should be, preferably in the mother's room, while in the incubation period. An infant with congenital chickenpox also needs isolation and treatment, but may remain with the mother. If a mother was exposed to chickenpox 6 to 20 days before delivery, and she has no history of chickenpox, she and her infant need to be isolated while it is confirmed by serology whether she is susceptible, and VZIG should be given to the infant if the mother develops lesions within 48 hours of delivery. The mother and infant may be discharged home together. If a mother develops the varicella rash postnatally, the infant has already been heavily exposed, and breast milk antibodies may decrease the severity of the infant's infection.

Epstein-Barr Virus

EBV, a B-lymphotropic herpesvirus, is among the most prevalent of human viruses. More than 95% of pregnant women are seropositive. When EBV infects adolescents, it may cause infectious mononucleosis, but most infections are asymptomatic. Humans are the only natural host for the virus; as is typical of herpesviruses, the virus is excreted intermittently during reactivations for the remainder of the individual's life. Transmission seems to require close, personal contact, via saliva. Infection is endemic year-round. Blood transfusion has also been documented to transmit virus occasionally.

Primary infection is rare during pregnancy because nearly all pregnant women are immune. The virus can be detected in cervical secretions by DNA hybridization. IgG and IgM to the viral capsid antigen can be detected in the acute infection, whereas IgG to the EBV nuclear antigen is detectable during latent infection.

Several studies have associated the occurrence of a primary infection in the first trimester of pregnancy with an adverse outcome, including prematurity, spontaneous abortion, and growth restriction. EBV can cross the placenta and has been shown to cause placental infection, but the pregnancy outcome seems to be normal, with rare cases of congenital anomalies reported.

A case-control study of more than 400 children with acute lymphoblastic leukemia showed an association of maternal infection with EBV at 12 to 14 weeks' gestation.[81] Further study indicated reactivation may also be associated with non–acute lymphoblastic leukemia childhood leukemia.[143] Finally, using quantitative real-time PCR to detect viruses in the tissue of infants who died of sudden infant death syndrome compared with controls, there was a statistical association with EBV and HHV-6[5] and sudden infant death syndrome.

Human Herpesvirus 6 and 7

The role of the T-lymphotropic viruses HHV-6 and HHV-7 in human infection is just emerging because HHV-6 was identified relatively recently in 1986, and HHV-7 was identified even later. They are double-stranded DNA members of the *Roseolovirus* genus of the herpesvirus family. There is only one variant of HHV-7, but two variants of HHV-6, A and B. Reflecting the high seroprevalence in adults, most infants have maternally acquired HHV-6 and HHV-7 IgG antibody, which wanes over the first 6 months of life, at which time these infants become seronegative and more susceptible to infection. HHV-6B infection is common in infants 6 to 12 months old, and most children are seropositive by 2 years of age. HHV-7 is acquired later than HHV-6, but is usually acquired by 5 to 6 years of age. After infection, the virus persists for life and is shed in the saliva, which is recognized as the major source of transmission.

About half of infants with primary HHV-6 infection are afebrile, although infants infected at younger than 6 months of age were more likely to be febrile than infants infected after 6 months.[164] Symptoms were present, however, in more than 90% of cases of primary infection, and one fourth of the infants were diagnosed with infantum subitum (roseola). Persistent and reactivated infection has not been shown to cause illness, but does persist in the brain, and HHV-6 has been implicated in a few cases of meningitis and encephalitis in infants and in children younger than 2 years. It is also associated with status epilepticus in these febrile infants. In a study of hospitalized children with encephalitis or severe febrile seizures, HHV-6B and HHV-7 were shown to be equally responsible for nearly one fifth of the cases in the first 2 years of life.[155]

HHV-6 is the only herpesvirus that can integrate its genome into the human chromosome, and many authorities hypothesized that HHV-6 congenital infection is inherited chromosomally and not transferred across the placenta.[142] There are no cases of congenital HHV-7, which also cannot integrate into the chromosome.[47] About one third of congenital HHV-6 infections are caused by HHV-6A. The remaining two thirds are caused by HHV-6B. All cases seem to be asymptomatic.[47] This is in contrast to later HHV-6 infections in infancy, all of which are due to HHV-6B. Congenital HHV-6 infections can be inherited from the chromosomes of either parent or both. Congenital infection was found in 1% of American infants, a rate similar to other Western European countries.[47]

Diagnosis remains difficult. Indirect immunofluorescence can be used to distinguish HHV-6 from HHV-7 IgG antibody and can be followed in serial titers. Also, antigen detection can be used to determine active HHV-6 and HHV-7 infections.

PARAMYXOVIRUSES

Paramyxoviruses are being increasingly noted as significant causes of human disease. Their spectrum has been greatly expanded with the discovery of human metapneumovirus (hMPV). They are single-stranded, RNA viruses with a lipid envelope. Among the human pathogens, there are two subfamilies. The Paramyxovirinae subfamily includes the parainfluenza viruses (PIV) and the mumps and measles viruses. HMPV belongs to the other subfamily, the Pneumovirinae, along with the related respiratory syncytial virus (RSV).

Parainfluenza Virus

PIV are enveloped RNA viruses in the Paramyxoviridae family. The four antigenic types (1 through 4) belong to the same subfamily as the mumps and measles (rubeola) viruses. Spread occurs through direct contact with infected respiratory secretions, via either respiratory droplets or contact with contaminated secretions on fomites. PIV 3 has been shown to survive for at least 10 hours on nonabsorptive surfaces (countertops) and 4 hours on absorptive surfaces, such as hospital coats, but die within minutes on finger pads.[7,16] Infection may occur year-round, but seasonal or nosocomial outbreaks also occur. PIV 1 and 2 outbreaks of croup or other respiratory illnesses tend to occur in the fall, whereas PIV 3 outbreaks are more likely in the spring and summer.

Nearly everyone is infected with all PIV types by 5 years of age. PIV 3, the most common cause of respiratory illnesses of all the serotypes, is also the most common type in infants younger than 12 months of age, infecting about half of them in that first year.[157] PIV 3 seems to spare infants in the first 4 months of life, owing to the presence of transplacentally acquired neutralizing antibodies, but it is the usual source of nosocomial nursery outbreaks, spread via health care workers.[43,92,99] Older, convalescing preterm infants seem to be at increased risk of severe disease in nursery outbreaks, consistent with waning levels of maternally acquired antibody.[99] The incubation period is 2 to 6 days, and virus may be shed for 3 weeks or more from infected infants. Immunity is incomplete, so reinfection may occur with all of the serotypes, but mostly only cause mild upper respiratory infections.

Parainfluenza infections have been regarded as second in frequency to RSV as a cause of respiratory infections. Rhinovirus seems to be more common in respiratory infections, however, and the more recently discovered hMPV is also probably more common than parainfluenza. As a group, PIV are responsible for upper respiratory infections, laryngotracheitis (croup), bronchiolitis, and pneumonia. PIV 1 and 2 are more likely to cause croup, whereas PIV 3 is highly associated with bronchiolitis and pneumonia, particularly in infants and young children. Respiratory infections from PIV may be difficult to differentiate clinically from infections caused by RSV. In young children and infants, they tend to be mild and have a very low mortality. Infected children may require supplemental oxygen, but rarely need ventilatory support. A few infants are asymptomatic. PIV have been identified as a cause of 13% of community-acquired pneumonia in infants.[80] Coinfection with other respiratory viruses may occur in 20% to 60% of infants and may worsen the severity of the infection.[26] In newborns, the infection is more similar to a severe RSV infection. Infants may have apnea, bradycardia, and pneumonia and there may be worsening of chronic lung disease.[43,92,99,157]

PIV may be diagnosed by isolating the virus from nasopharyngeal secretions; by rapid antigen detection techniques, such as immunofluorescent detection; and by PCR antigen detection. Serologic detection is not helpful. Prevention of nosocomial infections requires strict adherence to contact and respiratory precautions and strict hand washing. Severely ill infants must be monitored closely for oxygenation and need of ventilation. Severe laryngotracheobronchitis has been treated with epinephrine and corticosteroid aerosols, which decrease symptom severity and duration of hospitalization. Antibiotics may be used if there is bacterial superinfection.

Mumps

The mumps virus is another paramyxovirus, and humans are the only natural host. The virus is transmitted via respiratory droplets, saliva, and fomites. The incubation period ranges from 7 to 23 days, but is generally 14 to 18 days. The virus is readily isolated from saliva, urine, and CSF. Diagnosis is made by showing an increasing antibody titer. Respiratory isolation of any individual within the incubation period or with active mumps is recommended.

Clinically, the virus causes a prodrome of fever, malaise, and myalgia, usually followed by salivary gland swelling within 24 hours, then resolving within 1 week. The parotitis is usually bilateral and more often involves the parotid glands than the submaxillary glands; the sublingual glands are involved only rarely. Orchitis may rarely develop in infancy, but is usually found only in postpubertal boys, and rarely causes sterility. Likewise, aseptic meningitis and pancreatitis are uncommon complications usually found in older children. CSF pleocytosis is common, even without CNS symptoms. Finally, infection may be asymptomatic. Therapy is nonspecific and supportive.

There is no evidence that mumps is either more common or more severe among pregnant women compared with nonpregnant women. Deaths are exceedingly rare. Siegel and Fuerst[131] found no significant increase in risk of low birthweight among infants born to mothers with mumps when studied prospectively. In contrast, there is a considerable increase in the risk of a first-trimester (but not a second-trimester or third-trimester) abortion; the risk can be 27% among women with first-trimester mumps compared with a risk of 13% for uninfected, control women.

Although there have been multiple reports of birth anomalies after mumps in pregnancy, proof of association has been lacking, and studies using controls failed to find any increase in congenital malformations. There has been considerable discussion about a possible association of gestational mumps and infants with endocardial fibroelastosis. Statistical evidence is lacking, however, and the issue remains debatable.

Congenital and postnatal cases of mumps are exceedingly rare, and nearly always subclinical or very mild. Mumps as a cause of parotitis or aseptic meningitis is rare; even mothers with active mumps rarely infect their infants. There have been a few cases of mumps pneumonia in infants causing severe respiratory distress and death. There have been no reports of nosocomial epidemics of mumps in the nursery; transmission within the hospital is possible, although rare.

Rubeola (Measles)

The measles virus is also a paramyxovirus, has an RNA core and a lipid envelope. Humans are the only natural hosts.

TRANSMISSION

Rubeola is the most infectious of the childhood viral illnesses. It is most commonly found in late winter and in spring in temperate climates. The virus is usually transmitted via respiratory droplets, but may be airborne. Individuals are infectious from the onset of the prodrome (3 to 5 days before onset of the rash) until 4 days after the onset of the exanthem. The incubation period is usually 10 to 12 days, but it is difficult to recognize the time of exposure because patients are infectious during the prodrome. There is a 5% vaccine failure rate in individuals who receive only a single dose of the vaccine, and most endemic cases in the United States occur in these individuals with waning immunity or in infected individuals who have just entered the United States.

Transplacental, hematogenous transmission may also occur. In this instance, the fetus may have onset of disease virtually simultaneously with the mother, implying a large enough initial viral titer so as not to require further viral replication and viremia in the fetus.

LABORATORY DIAGNOSIS

Although the virus may be cultured from nasopharyngeal secretions, blood, urine, or other specimens, it is difficult to isolate, so most diagnoses are made by serology. A significant increase in IgG antibody concentration can be used if acute and convalescent sera are obtained, but, most commonly, serum IgM titers are used. IgM may stay elevated for at least 1 month after the onset of the rash.

CLINICAL MANIFESTATIONS

Clinically, the prodrome of measles begins with fever, cough, coryza, and conjunctivitis (with photophobia) and ends with the development of myriad Koplik spots, tiny, red-ringed white spots on the buccal mucosa. The maculopapular exanthem then begins over the head and neck, spreading to the trunk and upper extremities, then to the lower extremities, and finally fading in the same order over 7 to 10 days.

Measles pneumonia, often complicated by bacterial superinfection, is the most serious complication and is the usual cause of death in children younger than 1 year. The mortality in the United States is only 0.1%, however. Measles encephalitis, leading to drowsiness, seizures, and coma, is uncommon, but may occur in newborns and has a mortality of 11% and the potential for significant morbidity. Otitis, croup, purpura, myocarditis, and subacute sclerosing panencephalitis may also occur.

EFFECTS ON THE PREGNANT WOMAN

The clinical course of rubeola in either a pregnant or postpartum woman is the same as in a nonpregnant woman. The earliest reports of overwhelming pneumonia (often associated with congestive heart failure) caused by infection during pregnancy were tempered by many others in which maternal morbidity and mortality were not increased. In the measles epidemic in the United States from 1988-1991, infection during pregnancy was again associated, however, with the more serious complications of pneumonia and hepatitis. The mortality was 3% to 8%.

EFFECTS ON THE FETUS

Measles during pregnancy does not seem to be teratogenic because few to no malformations have been reported among infants born to mothers infected during epidemics. There are reports of fetal losses with infection during pregnancy. Measles also seems to be responsible for premature delivery, and these deliveries occur during or shortly after the acute illness. Some infants have experienced growth restriction.

PERINATAL MEASLES

Perinatal measles includes infections acquired transplacentally and infections acquired postnatally. Infection is assumed to be transplacental in origin if it occurs before 10 days of life. Most infants born to mothers with measles at or just before delivery remain uninfected, however, and are later susceptible to disease. The disease itself may be mild, but may also be fatal, and is often associated with pneumonia, particularly among infants born prematurely. Postnatally acquired rubeola is usually mild with minimal mortality. Of great concern are more recent reports of infants infected with measles before 2 years of age who have gone on to develop subacute sclerosing panencephalitis without the prolonged incubation period normally seen. They become ill with rapidly progressive disease before 5 years of age.[30]

THERAPY AND PREVENTION

The therapy for measles is usually symptomatic. No specific antiviral therapy is available. Ribavirin is not licensed for use in the treatment of measles. Vitamin A is recommended in regions where vitamin A deficiencies are recognized, or where the mortality of measles is greater than 1%. Some infants and children in the United States have vitamin A deficiencies. Infected patients should be isolated, and the isolation should include precautions against airborne transmission. Exposed, unimmunized individuals may be given measles vaccine, which sometimes affords protection.

Nonimmunized pregnant women and newborns who have no history of rubeola and who are exposed should be given immune globulin, 0.25 mL/kg preferably within 72 hours of exposure. The live attenuated measles vaccine should be administered to infants at 12 to 15 months of age, when maternally transferred antibodies are beginning to wane. The dose should be repeated at school entry to ensure that individuals with waning immunity are protected. The vaccine is contraindicated in pregnancy. Susceptible women who deliver in the incubation period or with rubeola need to be isolated from their infants if the infant is not born with a rash. Only immune staff and visitors may be allowed in the room. Immune globulin should be given to the mother and infant, preferably within 72 hours of exposure or immediately after delivery, if no rash is present. If siblings at home have measles when a susceptible mother and infant are discharged, the mother and infant should receive immune globulin.

True prevention of rubeola lies in maintaining a highly immune status in the population. This maintenance of immunity necessitates second vaccine doses to young adults, which is particularly important now that women are becoming pregnant at an older age, at which time their immunity may be waning, especially if they received only a single vaccination as a child. It has also been shown that preterm infants, born before 32 weeks' gestation, have very low levels of transplacentally transferred antibody, and are susceptible to infection by 6 months postnatally. Extremely preterm infants vaccinated at 15 months of age show an antibody response that is similar to that of term infants, however. It is particularly important that pediatricians continue to emphasize to their patients' families that MMR vaccination has *never* been shown to have a causal relationship with autism, despite the performance of numerous very large studies.

Respiratory Syncytial Virus

RSV is now recognized to be the most common respiratory pathogen in infants and children, infecting nearly all children by 2 years of age and reinfecting about 50% of children each year. In the United States, about 2% to 3% of infants younger than 1 year are admitted to the hospital with bronchiolitis, and most of them (60% to 70%) are infected with RSV. The mortality is roughly 2 per 100,000 infants. RSV usually causes a mild upper respiratory infection, but may be responsible for severe pneumonia and bronchiolitis, especially in high-risk populations. RSV usually occurs in the winter to early spring months in temperate climates, with a few relatively isolated infections during the rest of the year. This season overlaps that of other respiratory viral pathogens, so coinfections are common (about 20%). It is unclear how this affects disease severity. HMPV has roughly the same season as RSV and is increasingly being found to coinfect with RSV, now that it can be identified, but rhinovirus and adenovirus are also commonly found with RSV; influenza, parainfluenza, and newer coronaviruses are found less commonly. Infection is predominant in tropical climates during the rainy season.

RSV is a single-stranded, enveloped RNA paramyxovirus that can be divided into A and B types and divided further into subtypes. Both types may be present during epidemics, although one type is usually predominant. Although viral load seems to correlate with severity of infection, the subtype does not seem to correlate with severity, clinical course, or outcome. Because there is a 50% sequence divergence between type A and type B, infection with one type does not protect against infection with the other. Also, immunity is incomplete, and reinfection commonly occurs among infants, children, and adults. The viral genome encodes for 10 different proteins. Two surface proteins are particularly important. The fusion (F) protein is similar in all strains. It is responsible for the cell fusion, or syncytium, for which the virus is named. The G glycoprotein is an attachment protein, and it is responsible for the strain differences.

A few infants are infected with RSV during the first 3 weeks of life when levels of transferred maternal neutralizing antibody are at their highest. Infants with the highest antibody concentrations may have less severe infections. The effect of antibody in breast milk is inconsistent.

TRANSMISSION

Transmission of RSV most commonly occurs by direct contact with infected secretions from hand to nose or eye. Humans are the only source of the virus. Hospital staff play a major role in nosocomial spread of RSV via this mechanism, which can be addressed effectively with good hand washing. Transmission may also occur via aerosolized droplets or via fomites because live virus may be isolated for ½ hour from skin, 2 hours from gowns and gloves, and 1 day from glass or plastic. Viral shedding usually occurs over 3 to 8 days, but may last for weeks in high-risk or immunocompromised children. Incubation may be 2 to 8 days. Nursery epidemics have been described for RSV bronchiolitis and pneumonia, some simultaneously with parainfluenza and rhinovirus. In such epidemics, a third of the nursery staff may be infected, and this may be the cause of much of the spread within the nursery.

CLINICAL MANIFESTATIONS

Children in high-risk groups, particularly children who have pulmonary hypertension, heart disease, and lung disease, have a greater likelihood of severe disease, hospitalization, and mortality. Premature infants are particularly likely to require hospitalization if they have bronchopulmonary dysplasia, but are still 10 times more likely to be rehospitalized than term infants with RSV even if they do not have chronic lung disease. They are also more likely to be rehospitalized with RSV disease if they are discharged between September and December. Children with cyanotic or complex congenital heart disease are noted to have a higher mortality, and children who are immunocompromised or have cystic fibrosis are more likely to have severe disease, a higher mortality, and pneumonia. Long-term corticosteroid therapy seems to prolong the duration of viral shedding, and has not been shown to decrease the severity of disease. Finally, healthy infants younger than 6 weeks of age are more likely to develop lower respiratory tract infection, have a prolonged hospitalization, and require intensive care.

There have been numerous studies to determine risk factors for infection with a fair amount of variation in results. Because 3% to 5% of all infected infants are born at 33 to 35 weeks' gestation, the cost of administering palivizumab to all is prohibitive, and palivizumab is usually limited to infants at higher risk. High risk factors include preterm birth, chronic lung disease of prematurity, postnatal age of less than 6 to 10 weeks at the onset of the RSV season, congenital heart disease, neurologic disease, and immunodeficiency. Most studies report increased risk from other children, but this is variously documented as having two or more siblings, having school-age siblings or preschool-age siblings, or attending daycare.

Some reports find disease associated with the adverse effects of maternal prenatal smoking on lung growth and development in the fetus, whereas others indicate a worse effect secondary to smoking within the home. In the United States, Hispanic infants and Native American and Alaskan infants are more likely to be hospitalized than infants in the general population. Other reported risk factors include small for gestational age (<10% birthweight), male gender, multiple birth, cystic fibrosis, and family history of eczema. Reports vary concerning a family history of asthma or the effects of breast feeding.[15,37,119,125,126]

Young infants with infection may be asymptomatic. When symptoms occur, they are often nonspecific or are mild upper respiratory symptoms, such as a clear nasal discharge, cough, and coryza. Some infants have presented with respiratory arrest secondary to apnea. Others have simply developed bradycardia. Dyspnea, cyanosis, pulmonary infiltrates on chest radiograph, wheezing, respiratory decompensation, and fever all are well described. About two thirds of young children develop bronchiolitis, and one third develop pneumonia. Very premature infants may have minimal respiratory symptoms at first and may simply present with poor feeding, irritability or lethargy, and apnea. Fifty percent of infants may also have otitis media.

Although most febrile infants with bronchiolitis have a low risk of concurrent bacterial infection, the risk is significantly higher in preterm infants. Resch and colleagues[123] reported that 9.5% of infants born at less than 37 weeks' gestation had concurrent bacterial infections compared with 3.1% of term infants. Hospital stay was more than doubled. Infections tend to be in the urinary tract and tracheal aspirate, and some occur in the bloodstream.

The diagnosis is usually made rapidly from anterior nasopharyngeal or nasal swabs using immunofluorescent and enzyme immunoassay techniques that have a variable sensitivity, depending on the assay used. Culture of secretions or lung biopsy is possible, but results in a delayed diagnosis. Serologic testing is of limited value, particularly in young infants. PCR may also be used to detect antigen. Infections with parainfluenza, rhinovirus, adenovirus, and hMPV may mimic RSV infection in an infant.

SUBSEQUENT RESPIRATORY MORBIDITY

Infection with RSV, particularly in the first year of life, in term infants may result in chronic respiratory sequelae; this has been documented consistently in all clinical studies.[138] Term infants hospitalized for RSV bronchiolitis are three times as likely to have recurrent wheezing and 10 times more likely to need bronchodilators at 10 years of age.[105] Likewise, the prevalence of asthma at 7½ years of age was 30% among infants hospitalized for RSV bronchiolitis, but only 3% in controls.[132] In contrast, the incidence of asthma as a diagnosis is significantly less (50%) among 7-year-olds who had two or more uncomplicated upper respiratory infections, or "colds," before 1 year of age.[57,73,138] RSV bronchiolitis in the first year of life increases the likelihood of recurrent wheezing, but may or may not increase atopy.[52] The incidence of recurrent wheezing seemed to decrease in the longer duration studies, but there may be some abnormalities in pulmonary function even in adults. It is unclear why these infants are more predisposed to recurrent wheezing. Severe infection may be a marker for a genetic predisposition, or RSV bronchiolitis may induce long-term changes in the lungs when infection occurs at a certain developmental stage.[73]

Preterm infants are more likely to be infected with RSV and to develop more severe lower respiratory tract disease than term infants. Preterm infants, particularly if they develop chronic lung disease of prematurity, have smaller airways and are more likely to become obstructed with mucus, necrotic tissue, and edema. They are also more likely to have immature immunity and to lack significant maternal transfer of antibodies. Likewise, term infants with abnormal pulmonary function resulting in a smaller size of the airways are predisposed to developing severe lower respiratory tract infection with RSV. Similarly, Broughton and colleagues[18] showed that preterm infants with increased respiratory resistance at discharge from the NICU at 36 weeks' corrected gestational age were more likely to develop symptomatic RSV infections. On follow-up at 1 year of age, preterm infants who had RSV infections have significantly higher airway resistance, but similar lung volume, as controls.[19] Finally, preterm infants treated with palivizumab who were not hospitalized for RSV were less likely to develop recurrent wheezing (13%) compared with all preterm infants who did not receive palivizumab (26%) and compared with untreated preterm infants who were also not hospitalized for RSV (23%).[134]

PROPHYLAXIS AND THERAPY

The primary treatment for RSV infection is supportive care and includes oxygen therapy to correct hypoxemia, mechanical ventilation as needed, and hydration. Care must be taken to prevent hyponatremia because infants with bronchiolitis have elevated levels of antidiuretic hormone. Bronchodilators are frequently used. A Cochrane review of eight randomized trials of bronchodilators showed a significant improvement in clinical scores, but no improvement in oxygenation or rates of hospitalization.[64] Likewise, nebulized epinephrine has not been shown to be beneficial. Corticosteroids are not recommended for bronchiolitis in infants. Palivizumab is also not recommended for treatment of infection because it has not shown any efficacy.

A Cochrane review of 12 trials lacked the power to provide firm conclusions regarding the use of ribavirin. Three small trials within the 12 studies may indicate reduced days of mechanical ventilation and hospitalization and, possibly, recurrent wheezing,[149] but this was unclear. Weighing against these findings are the cost of treatment and potential toxic risks to the patient and staff, so ribavirin use is extremely limited, or it is not used at all. Inhaled nitric oxide and extracorporeal membrane oxygenation have been used for respiratory failure. Most infants do not need antibiotic coverage; possible exceptions are infants needing intensive care and preterm infants.

Infected infants should be isolated with contact precautions. Use of gowns and gloves supplemented with mask and goggle use has decreased hospital spread. Staff members should not care for infected and uninfected infants simultaneously. The education of staff and family must include hand washing before and after patient care. In the event of an epidemic, there should be laboratory screening for RSV infection and segregation of infected and uninfected patients and staff. There are no data on the use of RSV immune globulin in an epidemic.

The primary defense against RSV infection should be avoidance of high-risk settings. The families of all high-risk infants should be instructed in avoidance behavior and careful hand washing.

RSV immune globulin intravenous was made from donors who have high serum titers of neutralizing antibody to RSV and was licensed in 1996 by the FDA for prophylaxis of severe lower respiratory tract disease in children younger than 2 years of age at high risk because of bronchopulmonary dysplasia or preterm birth at 35 weeks' gestation or less. It is no longer available, having been replaced by palivizumab.

Palivizumab, a humanized mouse monoclonal IgG_1 antibody, was licensed by the FDA in 1998. The product consists of 95% human amino acids and 5% mouse amino acids. The mouse sequence for antigen binding was grafted to gene segments coding for human IgG; this prevents an antimouse reaction on repeated use. This antibody binds to the F protein of the virus and is active against A and B viral strains. It is given intramuscularly every 30 days, beginning in early November, for a total of five doses, at a dose of 15 mg/kg. Efficacy is similar to that of RSV immune globulin intravenous (a 55% reduction in hospitalizations because of RSV in high-risk infants),[58] but it does not prevent otitis media or hospitalizations for other respiratory viruses. It is much easier to administer.[45] There was no increase in adverse effects over controls. Also, palivizumab does not interfere with other vaccinations. It is not effective, and not approved, for treatment of RSV infections.

A trial of palivizumab for infants with acyanotic and cyanotic congenital heart disease showed a 45% reduction in RSV hospitalizations (9.7% versus 5.3%) with the larger decrease in infants with acyanotic lesions.[35] Adverse events and deaths were similar in treated infants compared with infants who received a placebo. Also, a 58% reduction in palivizumab serum concentrations was noted after cardiopulmonary bypass.

In Spain among infants less than 33 weeks' gestation, the rate of rehospitalization was at least 13.4% for lower respiratory disease because of RSV, when the infants did not receive any RSV prophylaxis. In addition, 11% of the infants were rehospitalized twice in 1 year for RSV. Prophylaxis for RSV should be continued for the entire season, even after the infant has been infected during the season. Cost-benefit analyses vary widely, but prophylaxis with palivizumab is very expensive, to the point that the cost is prohibitive for prophylaxis of all preterm and other at-risk infants. Recommendations for prophylaxis vary from country to country depending on population data.

The AAP recommends RSV prophylaxis for the following[94]:

1. Infants and children younger than 2 years old with chronic lung disease of prematurity who have required medical therapy (oxygen, bronchodilator therapy, diuretics, or steroids) within the 6 months before the onset of the season. These children may receive a maximum of five monthly doses. This may extend to two seasons, although the efficacy of treatment for a second season is not proven.
2. Infants born before 32 weeks' gestational age (31 weeks, 6 days, or less), even in the absence of chronic lung disease of prematurity.
   a. Infants born at or before 28 weeks, 0 days' gestational age, may benefit in their first season, whenever it occurs in the first 12 months of life.
   b. Infants 29 to 32 weeks' gestational age may benefit when they are 6 months of age or younger at the beginning of the season (a maximum of five monthly doses).
3. Infants who are 32 weeks and 0 days' gestational age to 34 weeks and 6 days at birth, and younger than 3 months of age at the start of the RSV season, and either attend daycare or have a sibling younger than 5 years of age.
   a. These infants may receive a maximum of three monthly doses, so that they are protected when they are at greatest risk for hospitalization.
   b. Table 39-31 provides a guideline for use of palivizumab.
4. Children who are 24 months or younger who have hemodynamically significant cyanotic and acyanotic congenital heart disease. Infants most likely to benefit include:
   a. Infants receiving medication for congestive heart disease.
   b. Infants with moderate to severe pulmonary hypertension.
   c. Infants with cyanotic heart disease.

TABLE 39–31 Maximal Number of Palivizumab Doses for Respiratory Syncytial Virus (RSV) Prophylaxis of Preterm Infants without Chronic Lung Disease, Based on Birth Date, Gestational Age, and Presence of Risk Factors[*]

	MAXIMAL NUMBER OF DOSES		
Month Of Birth	*<28 Weeks, 6 Days' Gestation and <12 Months of Age at Start of Season*	*29 Weeks, 0 Days through 31 Weeks, 6 Days' Gestation and <6 Months of Age at Start of Season*	*32 Weeks, 0 Days through 34 Weeks, 6 Days' Gestation, and with Risk Factor[†]*
Nov. 1–Mar. 31 of previous RSV season	5[‡]	0[§]	0[¶]
April	5	0[‡]	0[¶]
May	5	5	0[¶]
June	5	5	0[¶]
July	5	5	0[¶]
August	5	5	1[¶]
September	5	5	2[¶]
October	5	5	3[¶]
November	5	5	3[¶]
December	4	4	3[¶]
January	3	3	3[¶]
February	2	2	2[¶]
March	1	1	1[¶]

[*] Shown for areas beginning prophylaxis on November 1. If infant is discharged from the hospital during RSV season, fewer doses may be required.

[†] Risk factors: infant attends childcare or has a sibling <5 years old.

[‡] Some of these infants may have received one or more doses of palivizumab in the previous RSV season if discharged from the hospital during that season; if so, they still qualify for up to five doses during their second RSV season.

[§] Zero doses because infant will be >6 months old at beginning of RSV season.

[¶] Zero doses because infant will be >90 days of age at beginning of RSV season.

[¶] On the basis of the age of patients at the time of discharge from the hospital, fewer doses may be required because these infants will receive one dose every 30 days until 90 days of age.

American Academy of Pediatrics: Respiratory Syncytial Virus. In: Pickering LK, Baker CJ, Kimberlin DW, Lang SS, eds. Red Book: 2009 Report of the Committee on Infectious Diseases. 28th ed. Elk Grove Village, IL: American Academy of Pediatrics 566, 2009.

The AAP also recommends:

1. The RSV season usually begins in November or December, peaks in January or February, and ends in March or April. In the United States, the season tends to start the earliest in the South and the latest in the Midwest, but timing and severity may vary from year to year. When palivizumab is begun in early November and continued for five total doses, the infant has protective serum levels beyond the 20 weeks of treatment. The use of any additional dose is costly and not recommended.
2. The influenza vaccine should be given after 6 months of age before and during the influenza season.
3. Infants who have had cardiopulmonary bypass for surgical procedures experience a 58% decrease in serum levels and should be redosed as soon as they are medically stable.
4. There is no increased RSV risk in the following circumstances, and palivizumab is not indicated:
    a. Infants with hemodynamically insignificant heart disease, including:
        (1) Secundum atrial septal defect.
        (2) Small ventricular septal defect.
        (3) Pulmonic stenosis.
        (4) Uncomplicated aortic stenosis.
        (5) Mild coarctation of the aorta.
        (6) Patent ductus arteriosus.
    b. Infants with lesions adequately corrected surgically, unless still needing medication for congestive heart failure.
    c. Infants with mild cardiomyopathy, not receiving medical therapy.
5. Palivizumab has not been evaluated in randomized trials for immunocompromised children, so specific recommendations cannot be made. Prophylaxis may benefit a child with severe immunodeficiency, however.
6. Palivizumab is not effective in treating RSV disease or licensed for treatment of infection.
7. Prophylaxis should be continued even if a child experiences a breakthrough RSV infection during the season because some infants have been hospitalized more than once in a season for RSV lower respiratory tract infection. Also, multiple RSV strains may circulate during the same season.

8. The drug should be used within 6 hours of opening the vial because there is no preservative.
9. Patients with cystic fibrosis may be at increased risk of RSV infection, but the effectiveness of palivizumab is unknown.
10. If an RSV outbreak occurs in a high-risk unit, proper infection control measures should be used. Data do not support the use of palivizumab.
11. Palivizumab does not interfere with the responses to other vaccines.

Efforts toward development of a vaccine for active prevention of disease have been hampered by the results of the trial of the formalin-inactivated RSV vaccine, in which vaccinated infants had more severe disease and were more likely to die than nonvaccinated infants, possibly because the vaccine interfered with the secretory and neutralizing antibody response to the virus, allowing more active replication.

Human Metapneumovirus

Discovered in Holland in 2001, hMPV is an enveloped, negative-sense RNA virus of the Paramyxoviridae family, in the same subfamily with and sharing many clinical characteristics of RSV. There are four major genotypes: A1, A2, B1, and B2. All four genotypes circulate simultaneously throughout the season, but in varying proportions. It is unclear what effect this simultaneous circulation has on immunity, and whether certain genotypes are more virulent than others. hMPV is difficult to grow in the laboratory and has escaped detection, but can now be identified by PCR.

A large proportion of previously unidentifiable causes of respiratory tract disease in children and adults have been attributed to hMPV, and it is associated with upper and lower tract disease. Virtually all children are infected by 5 years of age,[8] and infection may be recurrent throughout life. hMPV seems to be second only to RSV as a cause of bronchiolitis in children younger than 1 to 2 years of age.[21] Although RSV is most common in infants younger than 6 months of age, hMPV is more common in infants 6 to 12 months old.[40,108] hMPV occurs in epidemics, mostly in the winter and spring months, and overlaps seasonally with RSV. It may cause a coinfection with other respiratory viruses.[86] During epidemics, bronchiolitis may be caused by RSV or hMPV alone or together, and various other respiratory viral pathogens have been reported as coinfections. Under these circumstances, disease severity has variably been reported as more severe or unchanged. hMPV is also present in smaller numbers year-round. The virus is worldwide in distribution. Humans are the only known source of infection.

In one study of nasal wash specimens obtained over a 25-year period from newborns to 5-year-olds, hMPV was responsible for 20% of previously virus-negative lower respiratory tract infections, indicating that 12% of lower respiratory tract infection in these children (newborns to 5-year-olds) was due to hMPV.[162] In this cohort, the mean age of infected children was 11.6 months. Three quarters of all infections occurred in the first year of life. Infection primarily occurred between December and April and resulted in a 2% hospitalization rate.

Infection seems to be slightly less severe than with RSV. The disease spectrum included upper respiratory tract infection (15%), bronchiolitis (59%), croup (18%), pneumonia (8%), and asthma exacerbation (14%). Asymptomatic infection may occur, particularly in healthy children or adults. Others present with rhinitis, mild fever, a wet cough, or wheezing. Otitis has also been reported.[122] It is unclear whether premature infants or infants with underlying chronic pulmonary disease or cardiovascular disease are at greater risk. Pulmonary function seems to be adversely affected in preterm infants, but recurrent wheezing is seen in term infants as well. Infection is believed to occur via contact with contaminated secretions, and the incubation period apparently is 3 to 5 days. The duration of viral shedding is unclear, but may be prolonged in the face of immunodeficiency.

Hospitalized patients should be isolated with contact precautions and an emphasis on careful hand washing. Treatment is supportive. Respiratory monitoring is important and may indicate a need for oxygen or mechanical ventilation. Bacterial superinfection seems to be unusual.

HUMAN IMMUNODEFICIENCY VIRUS

Epidemiology

HIV-1 is the principal cause of AIDS. (See also Chapter 23.) In the United States, homosexual men still constitute most domestic cases. Disease contracted through intravenous drug abuse or heterosexual activity also is prominent, however, and in some areas, nonhomosexual transmission outranks that seen in gay men. The U.S. Centers for Disease Control and Prevention (CDC) estimated in 2006 that approximately 27% of all Americans diagnosed with HIV infection were women, most of whom were of childbearing age. Approximately 80% of women newly diagnosed with HIV infection acquired it through heterosexual contact. Women from minority populations are disproportionately HIV-positive. In the 2006 CDC estimates, the incidence of new HIV infection in African-American women was 56 per 100,000 and in Latina women was 14 per 100,000 compared with less than 4 per 100,000 in white women.

In contrast to the United States, most adult HIV infection in the developing world is contracted through heterosexual means. The incidence is highest in east and central sub-Saharan Africa, Southeast Asia, and parts of South America. In these areas, most HIV-positive patients are middle-aged adults, with the prevalence among childbearing women in some urban centers exceeding 30%. The debilitation and fatality from AIDS lead to the depletion of the heart of the workforce in tenuous economies and the orphaning of numerous uninfected offspring.

Currently, virtually all HIV-infected infants acquire disease from an infected mother. Consequently, most mothers of infected infants in the United States fall into a high-risk category—intravenous drug use or sexual activity with a man at high risk (bisexuality or intravenous drug use). Infected children follow a socioeconomic pattern nearly identical to that seen in HIV-1-infected women, and greater than 85% are from minority populations. Reflecting a medical success story of remarkable proportions, the incidence of perinatal HIV in the United States decreased nearly 80% in the latter half of the 1990s. In the first decade of the 2000s, only 100 to 200 cases of perinatally acquired HIV infection per year were reported to the CDC. Much of this decline was the result of increased voluntary HIV testing during pregnancy and the widespread application of intragestational prophylaxis with antiretroviral drugs. By contrast, in the developing world, where such care is largely unavailable, hundreds of thousands of infants are infected through perinatal transmission each year.

Pathogenesis

HIV is an RNA-containing retrovirus with an approximately 9.7-kb genome. The virus infects cells containing the surface molecule CD4+, most notably helper T lymphocytes and macrophages. An infected adult initially exhibits a robust immune response to the virus, with the appearance of HIV-specific antibodies and CD8+ cytotoxic T lymphocytes. After an initial mononucleosis-like syndrome, adults experience a prolonged period of clinical latency, characterized by the establishment of stable, low-level plasma viral titers (referred to as the *set-point*) and near-normal CD4+ T lymphocyte counts. During this period, the number of target cells destroyed by HIV is balanced by CD4+ cell repletion. This state may last for years.

Despite the healthy appearance of latently infected patients, HIV actively replicates in lymph nodes and circulating CD4+ cells and ultimately overwhelms the host, leading to increasing concentration of virus in plasma and tissues, clinical deterioration, and CD4+ cell depletion. This last phenomenon results in profound disruption of the immune system because CD4+ T cells coordinate many aspects of immunity. The host thereafter is placed at risk for acquiring infections with organisms that normally possess low pathogenicity (opportunistic infections) and AIDS-related cancers. The strongest predictor of progression of disease in adults is the concentration of plasma-borne virus, commonly referred to as the *viral load*. The viral load is measured by a quantitative reverse transcriptase PCR test, which is widely commercially available. The number of CD4+ T cells also is an additional independent predictor of disease progression in adults.

Generally, untreated children with perinatal HIV-1 infection experience more rapidly progressive disease than adults. Similar to other intracellular pathogens, it is likely that HIV infection of the fetus early in gestation, when NK and T cells are low in number and immature in function, results in particularly severe disease. Even in a full-term newborn, however, T cells possess multiple functional deficiencies that render the host particularly susceptible to pathogens such as HIV. Early HIV-specific cytotoxic T cell lymphocyte responses, which are crucial for the initial control of HIV infection in adults, frequently are sluggish or absent in infected newborns. There is evidence that fetal and newborn immune cells may provide better substrates for HIV infection or replication than mature cells because neonatal macrophages and memory T cells support HIV replication better than cells derived from adults. Consequently, infected newborns typically show very high plasma viral loads early in life, frequently registering hundreds of thousands to millions of viral RNA copies per millimeter of plasma by 4 weeks of age. Infants usually are unable to establish a set-point, reflecting poor early control of viral replication, and, as a result, show unmoderated high viral loads throughout early childhood.[130]

As in adults, the strongest predictor of disease progression in perinatally acquired HIV-1 is the plasma-borne viral titer. High viral loads in infancy presage major manifestations of HIV and death early in life. Several factors other than viral load also have been associated with disease progression in perinatally acquired HIV-1. Thymic dysfunction, manifested by the early depletion of CD4+ and CD8+ T cell populations, occurs in a small percentage of HIV-1-infected infants and is strongly associated with early severe disease. Coinfections with other pathogens in early life may detrimentally affect disease progression further. CMV in particular, long suspected of enhancing HIV-1 replication in adults through transactivating transcription factors, results in higher mean titers of HIV-1 and the early appearance of HIV-1–associated signs and symptoms and death in infants infected with CMV and HIV-1.

Mother-to-child transmission occurs in approximately 25% to 30% of infants born to mothers who have not taken antiviral medications during gestation. Intrauterine transmission has been shown directly by detection of virus in aborted fetal tissue. Most infants are negative for HIV immediately after birth, however, and become positive within the first several weeks after delivery, supporting the contention that most perinatal transmission occurs near the time of delivery or as the child traverses the birth canal. Cervical secretions harbor HIV in concentrations proportionate to concentrations in the bloodstream. Infection at or near the time of delivery, when the mucous membranes of the infant are exposed to infected maternal secretions and blood, is assumed to be the principal mode of acquisition of HIV perinatally.

The primary factor that places an infant at risk for perinatal HIV transmission seems to be the degree of maternal viremia during pregnancy and its correlates—severity of maternal clinical illness and CD4+ cell depletion.[41] In several studies, the risk of transmission was proportionate to maternal viral load. No level of maternal viremia is absolutely safe for the fetus, and transmission occasionally has been reported even when maternal viral load has been undetectable. Nevertheless, vertical transmission rates approaching zero have been associated with viral loads smaller than 500 to 1000 HIV RNA copies per mm of plasma. Other risk factors for perinatal transmission are less well established. The presence of chorioamnionitis and the occurrence of premature rupture of membranes have been suggested as risks for perinatal HIV transmission. Instrumentation during delivery, with the associated exposure of the newborn to infected maternal blood and cervical secretions, also increases risk of transmission. There also has been speculation that some viral genotypes may be more likely to cross from mother to child than others.

HIV infection from mother to child also may occur though the ingestion of contaminated breast milk. Breast milk contains virus in macrophages and in the cell free fraction, and the viral concentration in breast milk correlates with the concentration measured in the bloodstream. In the United States, where alternative infant nutrition is available, the impact of breast milk-related HIV transmission is negligible. The effect in the developing world is substantial, however. The excess incidence of mother-to-child transmission of HIV attributable to breast feeding is estimated to be 4% to 22%.

Although the risk of breast milk–related late postnatal transmission is highest in the first 6 months postpartum, transmission occurs throughout the duration of breast milk exposure.

Breast milk–transmitted HIV is believed to enter the infant either through the gastrointestinal mucosa or possibly through tonsillar lymphoid tissue. Several factors have been identified that increase the risk of breast milk transmission, including the duration of breast feeding, severity of infection in the mother, presence of breast lesions, and inflammation of the infant's gastrointestinal mucosa (particularly by *Candida* infection). Several immunologic and chemical factors in breast milk have been found to inhibit HIV growth in vitro, and the relative concentrations of these factors in a particular specimen may influence the risk of transmission.

Care of the Mother and Prevention of Vertical Transmission

Advanced HIV infection in the mother can adversely affect the outcome of the pregnancy, even if the infant is not infected. Studies performed in Africa indicate that women ill with HIV infection bear infants who are smaller for gestational age and more premature compared with women without HIV infection. Perinatal mortality also is increased. Infants born to asymptomatically infected women have negligible effects. These data suggest that factors covariate with advanced HIV disease, particularly malnutrition, secondary and coexisting infections, and illicit drug and alcohol use, are the most important factors mediating the immediate health of the newborn, and must be addressed appropriately during the obstetric care of the mother. All women should be placed on multivitamin supplements, and these should be continued after gestation.

CARE OF THE MOTHER AND INFANT IN DEVELOPED COUNTRIES

Intragestational and postgestational administration of antiretroviral drugs is extremely effective in preventing vertical transmission of HIV-1 and has become the standard of care in the developed world.[97] In a landmark prospective, multicenter, randomized trial conducted in the early 1990s (PACTG 076), zidovudine prophylaxis resulted in a reduction in vertical transmission from 25.5% to 8.3%.[27] The regimen employed in this study included three phases: (1) a maternal oral dose of 100 mg five times a day beginning between 14 and 34 weeks of gestation; (2) intrapartum intravenous zidovudine at 2 mg/kg of body weight over the first hour, followed by 1 mg/kg hourly until birth; and (3) infant oral dosing of zidovudine at 2 mg/kg every 6 hours for 6 weeks. In response to the success of this study, the CDC recommended wide application of the PACTG 076 protocol to limit vertical transmission of HIV in the United States. Subsequent experience indicated that in some populations intrapartum and postpartum use of zidovudine could result in a 5% or less transmission rate.

Even as public health recommendations for this regimen were being established, significant changes in antiretroviral strategies in HIV-infected adults were evolving that produced dramatic reductions in plasma-borne viral loads and in AIDS-related deaths. These changes included the administration of multidrug regimens (rather than monotherapy) and the early institution of antiviral medication based primarily on viral load rather than CD4+ T cell depletion or the presence of symptoms. As a result, by the late 1990s, many HIV-infected women entering pregnancy already were taking multidrug regimens (termed *highly active antiretroviral therapy* [HAART]) comprising various combinations of nucleoside reverse transcriptase inhibitors (sometimes, but not always, including zidovudine), non-nucleoside reverse transcriptase inhibitors, and protease inhibitors, to maintain their own health.

Based on these realities, and the observation that low maternal viral loads strongly correlate with protection of the newborn, the CDC updated its recommendations in 2002 and again in 2008. The full text of these guidelines and updated information can be accessed at http://AIDSinfo.nih.gov. These recommendations, along with additional recommendations by the AAP,[51] can be summarized as follows:

1. Pregnant women found to be HIV-positive should be started on HAART using the same criteria as in nonpregnant patients, based on viral load, CD4+ count, and presence of HIV-related symptoms. Genotypic testing of the infecting isolate should be pursued before initiating therapy to determine preexisting resistance to antiretroviral drugs.
2. Therapy should be continued in women who are already on multidrug HAART at the time that pregnancy is identified, assuming that the woman has had a satisfactory response (reduction of viral load, improvement or stabilization in CD4+ T lymphocyte count, and improved or stable clinical condition). For women with persistently high or increasing viral loads during pregnancy, alterations of therapy should be considered based on genotypic testing of the woman's HIV isolate to detect drug resistance–conferring mutations in a manner identical to nonpregnant subjects.
3. The CDC recommends adding zidovudine if not initially included in the woman's HAART regimen, even if the drug had been discontinued because of the emergence of zidovudine-resistant HIV. This recommendation is based on the observation that trials have consistently shown a protective effect of zidovudine against vertical transmission of HIV even in the presence of zidovudine-resistant isolates in the mother. Zidovudine possesses pharmacologic qualities (high concentrations of active, intracellular drug in the placenta and efficient transplacental transfer of drug to the fetus) that render it particularly attractive in the prevention of mother-to-infant transmission. Intravenous zidovudine should be initiated during labor regardless of the mother's HAART regimen. The CDC recommendations allow that some women should continue non–zidovudine-containing regimens if they have resulted in sustained nondetectable viral loads before pregnancy, particularly women infected with documented zidovudine-resistant organisms or organisms intolerant of zidovudine. In such cases, it is preferable to use alternative drugs to zidovudine with good placental penetration; generally, nucleoside reverse transcriptase inhibitors cross the placenta well, and protease inhibitors do not.
4. In the unusual HIV-infected pregnant woman who has not received prior antiretroviral therapy and whose own

condition does not warrant initiating such therapy, zidovudine may be administered as monotherapy for prevention of vertical viral transmission using the schedule defined by PACTG 076. This schedule should be applied even in women with low or undetectable viral loads.

5. The CDC guidelines suggest discussing the relative risks of administering antiretroviral therapy during the first trimester with the mother, although in most instances initiation or continuation of HAART is recommended if such therapy would be standard in the nonpregnant patient.
6. Most antiretroviral drugs are available only for oral administration. During labor or before elective cesarean delivery, the woman should continue to receive HAART according to her scheduled dosing with small sips of water whenever possible. Additionally, she should receive continuous-infusion intravenous zidovudine using the regimen employed by PACT 076 (a loading dose of 2 mg/kg followed by 1 mg/kg per hour) until the cord is clamped. This infusion is recommended even when zidovudine is not part of the woman's long-term regimen because of the possibility that zidovudine-susceptible viral subpopulations exist even in the face of overall zidovudine resistance.
7. The CDC recommends further that zidovudine continue to be used as monotherapy (2 mg/kg per dose orally, or 1.5 mg/kg intravenously, every 6 hours for 6 weeks) in the infant regardless of the mother's regimen or the length of her past experience with zidovudine, out of concern that the early institution of antiretroviral drugs other than zidovudine for prophylaxis may foster resistance to a broad range of agents. Dosing should be started as soon after birth as possible, ideally within 6 hours of birth. Despite this recommendation, many AIDS therapists choose to institute prophylaxis for the infant with the same drug combination that was effective in the mother, conceding that the safety and pharmacokinetics of many antiretroviral drugs other than zidovudine have not been determined in newborns. Some authorities recommend multiple-drug regimens, usually including zidovudine, for an infant born to a mother who received only intrapartum therapy or no antiviral therapy at all because in these circumstances the resistance phenotype of the mother's HIV isolate is unknown. The decision to use nonzidovudine antiretroviral drugs and the dosing of such therapy in the infant should be established in consultation with a pediatrician expert in the care of HIV infection. Because in many instances there is a delay in registering the infant for insurance, and because liquid forms of antiviral agents may be difficult to procure from community pharmacies, every effort should be made to supply the family with the infant's medications (not just a prescription) at discharge.
8. For premature infants (<35 weeks' gestation), zidovudine should be administered at 2 mg/kg per dose orally every 12 hours, or 1.5 mg/kg per dose intravenously, increasing to 2 mg/kg per dose every 8 hours at 2 weeks if 30 weeks' gestation or greater at birth or at 4 weeks if less than 30 weeks' gestation at birth. The dosing of antiretroviral agents besides zidovudine in premature infants has not been determined.
9. The mother should be counseled against breast feeding, whether or not she is continuing antiretroviral therapy after pregnancy.
10. HIV-exposed newborns should be immunized against hepatitis B, using the dose and schedule recommended for infants not exposed to HIV.

Other issues surrounding care of HIV-complicated pregnancy are discussed subsequently.

Safety

The effectiveness of HAART therapy in the mother and intrapartum and postpartum prophylaxis in the infant in decreasing the incidence of vertical HIV transmission is incontrovertible. By the early 2000s, transmission rates after applying this strategy were less than 2%. Despite a broad experience, concerns remain, however, regarding the safety of deliberate exposure of the pregnant woman, fetus, and young infant to antiretroviral drugs. The adverse effects of zidovudine exposure as defined by the PACTG 076 trial have been investigated through follow-up studies of mothers and children enrolled in this and similar trials. Mild and reversible anemia in infants occurs during the 6-week period of postnatal administration, but no further untoward effects have been consistently documented after years of observation.[98] Anemia may be more severe in an infant born to a mother who was receiving multiple antiretroviral drugs during pregnancy.

Some concern has been raised by European investigators that a small percentage of children exposed in utero to zidovudine may have persistent defects in mitochondrial function, a subcellular target of zidovudine in vitro. Older children and adults receiving long-term nucleoside reverse transcriptase inhibitors such as zidovudine occasionally develop a high anion gap acidosis because of mitochondrial dysfunction. Studies of a large cohort of European children exposed as fetuses and infants to antiretroviral therapy suggest that mitochondriopathies may occur in 0.26%, an incidence that is greater than 20-fold that expected in the general population. A retrospective evaluation of more than 16,000 uninfected, exposed American children failed to reveal any subject with symptoms consistent with a mitochondrial disorder.[98]

The safety of nonzidovudine drugs when administered during and immediately after pregnancy is less well studied. To date, these drugs seem to be remarkably free of adverse effects to the mother and the infant. The one probable exception is the non-nucleoside reverse transcriptase inhibitor efavirenz, which is teratogenic in primates at serum concentrations routinely achieved after conventional dosing in humans.[98] Although initial studies from Europe suggested that multidrug HAART therapy during pregnancy predisposed to preterm delivery, this finding was not supported by data collected in an American cohort of 369 women receiving combination therapy without protease inhibitors and 137 additional women receiving combination therapy with protease inhibitors.[146] Studies examining the effectiveness of zidovudine/lamivudine and short courses of the non-nucleoside reverse transcriptase inhibitor nevirapine in preventing vertical transmission of HIV in developing countries (see later) likewise have not shown toxicity from these drugs either to the mother or to the infant.

The use of selected agents should prompt careful monitoring of the mother. Prolonged courses of nevirapine occasionally have been associated with significant hepatotoxicity in pregnant women, especially when the CD4+ counts exceed 250/mm^3; such dosing requires frequent, serial liver function tests. Nucleoside reverse transcriptase inhibitors, especially the combination of stavudine and didanosine, rarely may be associated with the development of lactic acidosis in the mother during pregnancy. Data regarding potential toxic effects of a wide range of other antiretroviral drugs are being collected through long-term follow-up studies, and the clinician is encouraged to record all cases of antiretroviral drug exposure with the Antiviral Pregnancy Registry (see http://www.APRegistry.com).

Truncated Prophylaxis

Currently available information suggests that there is value to prophylactic antiviral administration even when the pregnant woman presents late in pregnancy. Observational data collected in New York indicate that, in nonresearch settings, the full three-phase course of prophylactic zidovudine (as prescribed by PACTG 076), started during pregnancy and extending into the intrapartum and postpartum periods, results in a relative risk of HIV vertical transmission of 0.23 (compared with no prophylaxis); that drug started only intrapartum, but including administration to the newborn, results in a relative risk of 0.38; and that drug given only to the infant, but started within 48 hours of birth, results in a relative risk of 0.35.[153] Prophylaxis initiated in the infant on the third day of life or later in the absence of maternal prophylaxis has no detectable effect. These data argue for the immediate initiation of antiretroviral prophylaxis regardless of when during pregnancy or delivery the mother is found to be HIV-positive.

For a woman in labor who has not received prior therapy, the ideal regimen is not established. The CDC recommends one of the following regimens, based on data generated in trials conducted in nonindustrialized settings (see later): (1) single dose of nevirapine during labor followed by a single dose to the infant within 48 hours of life, or (2) zidovudine and lamivudine during labor followed by 1 week of zidovudine and lamivudine to the infant, or (3) intravenous zidovudine to the mother during labor followed by 6 weeks of zidovudine to the infant, or (4) a combination of these schedules. Infants delivered to mothers who have received no therapy at all should be offered 6 weeks of zidovudine, with the addition of other antiretroviral drugs if zidovudine resistance is known or suspected in the mother's isolate; this prophylaxis should be initiated as soon after delivery as possible.

Prenatal Testing

The availability of effective prophylactic regimens against vertical transmission of HIV mandates routine prenatal HIV testing.[50] It currently is standard practice to add voluntary HIV testing to other prenatal screening tests. Most authorities recommend an "opt-out" strategy for prenatal HIV testing; that is, the test is performed routinely unless the woman specifically requests that it be excluded, assuming such a strategy is consistent with state statute. For women with negative test results exhibiting high-risk behaviors or residing in high-incidence areas, the assay should be repeated during the third trimester. Problems still exist in reaching selected populations of HIV-infected women, particularly women using illicit drugs, in a sufficiently timely fashion to prevent transmission to their offspring.

Given the effectiveness of even incomplete prophylactic schedules, rapid HIV testing should be offered to laboring women who have had no prenatal care. If the rapid test is positive, intravenous zidovudine should be initiated immediately in the mother until delivery, and oral zidovudine should be administered to the infant, even in the absence of a confirmatory HIV test (Western blot or viral detection assay). Breast feeding should be postponed until confirmatory testing is completed. Confirmation of the rapid test should be pursued as soon as possible after delivery, and the decision to continue zidovudine in the infant and to recommend or restrict breast feeding can be made according to the result of the confirmatory test. All women found to be HIV-positive during pregnancy should be screened for other frequently encountered coinfections—specifically tuberculosis, syphilis, toxoplasmosis, hepatitis B and C, CMV, and HSV.

Cesarean Delivery

Multiple studies have documented the benefit of delivering infants born to HIV-infected mothers by cesarean section. A meta-analysis of 15 observational studies indicated consistent and significant reductions in vertical transmission when elective cesarean delivery is offered to HIV-infected women. Nevertheless, the additional benefit gained by cesarean delivery is minimal in an adherent mother receiving HAART with a very low or undetectable viral load late in gestation. Cesarean section may be most appropriate for the HIV-infected woman unable to administer antiretroviral therapy to herself or her newborn or in a mother who has a persistently high viral load (>1000 copies/mL) despite multidrug therapy. Operative delivery also should be considered in an infected woman when viral load is unknown.

Elective cesarean sections should be scheduled at 38 weeks of gestation, and if possible should be performed while the membranes are intact. Premature rupture of the membranes decreases the benefit from cesarean delivery, but the duration of ruptured membranes beyond which operative delivery adds no benefit is unknown. Intravenous zidovudine should be initiated at least 3 hours before surgery, and other antiretroviral medications should be continued before and after delivery. Postpartum complication rates after elective cesarean section approximate the rates seen in noninfected women, although they are higher after emergent cesarean delivery and in women with advanced disease.

CARE OF THE MOTHER AND INFANT IN DEVELOPING COUNTRIES

The expense of perigestational prophylaxis using HAART, or zidovudine monotherapy as defined by the PACTG 076 protocol, prohibits use in most of the developing world, where most of the HIV burden lies. It is unusual for pregnant women in many nonindustrialized countries to present for prenatal care during the early stages of gestation. To have any practical applicability in these settings, regimens must be effective when offered late in pregnancy. Several trials conducted in the late 1990s and the early 2000s in Africa and Asia have shown the efficacy of selected abbreviated schedules of antiretroviral agents to interrupt vertical transmission of HIV in environments with limited health care resources. These protocols were developed with the recognition that they do not address at least some intrauterine infection, and that they do not provide prophylaxis against most breast milk–related transmission. The principal antiviral agents used in these trials have been zidovudine, lamivudine, and nevirapine. The results of representative seminal trials are described next.

Short-Course Zidovudine

Trials in Thailand (among non–breast-feeding women) and Côte d'Ivoire (among breast-feeding mothers) initially evaluated a truncated zidovudine regimen consisting of 300 mg twice daily to the mother starting at 36 weeks and then 300 mg orally every 3 hours during labor. No prophylaxis was administered to the infant. Compared with placebo, HIV vertical transmission at 6 months was reduced by half (9.4% versus 18.9% among placebo recipients).[129] This study was followed by a four-arm protocol in which zidovudine was initiated at either 28 weeks' gestation or 36 weeks' gestation in the mother, and infant prophylaxis was given either for 3 days or for 6 weeks. The long-long arm produced significantly better protection than the short-short arm (4.1% versus 10.5% at 6 months). The longer antepartum arm was also associated with a significantly lower incidence of in utero infection compared with the short antepartum arm.

These studies document protection by zidovudine even when administered for a shorter duration than that prescribed in the PACTG 076 protocol, although generally inferior to the protection produced by strategies employing the full PACTG 076 regimen or HAART regimens. Despite the additional benefit of longer treatment of the mother, it is uncertain if such a schedule can be successfully applied in practice. Experience in Kenya with a protocol initiating zidovudine at the relatively late date of 36 weeks of gestation documented that less than one quarter of HIV-infected mothers took the fully prescribed regimen.

Zidovudine and Lamivudine

The effectiveness of the combination of the two nucleoside reverse transcriptase inhibitors zidovudine and lamivudine in preventing vertical transmission of HIV compared with placebo was tested in a trial conducted in several African countries in breast-feeding mothers (PETRA trial).[114] The combination (300 mg of zidovudine and 150 mg of lamivudine twice a day) was initiated at 36 weeks' gestation and continued through labor and 1 week after delivery. The same two drugs were administered to the infant (4 mg/kg of zidovudine and 2 mg/kg of lamivudine orally twice a day) for the first week of life. Although significant benefit was seen at 6 weeks postpartum, there was only a nonsignificant trend toward benefit at 18 months (14.9% offspring infection versus 22.2% in the placebo group). Dosing limited to the intrapartum period resulted in vertical transmission rates equal to that recorded in the placebo group. Lamivudine-resistant HIV was subsequently isolated from some of the mothers who had received this drug, but frequently did not persist; the implications of this finding are uncertain.

Nevirapine

Nevirapine is a non-nucleoside reverse transcriptase inhibitor that characteristically produces a rapid, profound decrease in HIV viral load. Its prolonged use as a single agent is limited by the rapid emergence of resistance, but this phenomenon is less problematic when the drug is used short-term exclusively to prevent perinatal transmission of virus. HIVNET 012, a trial conducted in breast-feeding mothers in Uganda, administered a single 200-mg dose of oral nevirapine to the mother at the onset of labor and a single 2 mg/kg dose of nevirapine to the infant at 48 to 72 hours of age. The comparison group was administered zidovudine orally during labor (600 mg, followed by 300 mg every 3 hours), and zidovudine was administered to the infant for 1 week (4 mg/kg twice daily). The incidence of infection at birth was equal in both groups (approximately 9%), but significant advantages in the nevirapine group were apparent by age 6 weeks and continued until 18 months: 25.8% infection in zidovudine recipients versus 15.7% infection in nevirapine recipients ($P < .003$).[61] The nevirapine strategy has the advantage that only two doses are required, and maternal and infant doses can be given under direct observation. Although nevirapine-resistant HIV isolates have been detected in women enrolled in these trials, typically resistance disappears after several months, suggesting that the strategy can be reapplied to subsequent pregnancies.

Subsequent studies have been designed to examine the nuances of short-term antiretroviral drug administration to interrupt mother-to-child transmission of HIV. These studies have employed zidovudine, nevirapine, or a combination of the two, and have applied them either to the mother and the infant or only to the infant. Virtually all studies document superior interruption of vertical HIV transmission if the laboring mother and newborn infant receive an antiretroviral agent compared with administration only to the infant. Most studies suggest that when the infant receives single-dose nevirapine plus 1 or 6 weeks of zidovudine, the incidence of HIV transmission is lower than when only one of these drugs is used alone.

Clinical Manifestations

Virtually all infants born to an HIV-infected mother are asymptomatic at birth. Most HIV-infected offspring begin to show signs and symptoms within the first 1 or 2 years of life. A smaller proportion, termed *rapid progressors*, become symptomatic within 1 or 2 months after delivery. Infants with rapidly progressive disease have plasma viral loads early in life that are two or three times higher than the plasma viral loads of infants with more indolent infection.

With the exception of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia, most opportunistic infections occur late in the course of the child's illness. *P. jiroveci* pneumonia commonly manifests in the first months of life. In contrast to *P. jiroveci* pneumonia in adults, virtually all of whom have preexisting immunity to *Pneumocystis* before acquisition of HIV, *P. jiroveci* pneumonia in infants is due to primary infection in the absence of preexisting immunity, and results in severe, frequently overwhelming, bilateral pneumonia. Other characteristics of untreated or poorly controlled perinatal HIV infection are nonspecific. Recurrent bacterial infections are frequent in infants with HIV infection. Most of these are minor (e.g., otitis media), but some are severe (bacteremia, pneumonia, or meningitis). Other commonly encountered early manifestations include persistent mucocutaneous candidiasis, abdominal organomegaly, diffuse lymphadenopathy, chronic diarrhea, failure to grow, and developmental delay. Children also acquire a diffuse, interstitial pneumonia of uncertain origin termed *lymphocytic interstitial pneumonia*. HIV-specific cancers, such as B cell lymphomas, Kaposi sarcoma, and leiomyosarcomas, are unusual in children and generally occur late in the course of the illness.

Diagnosis and Care of Infants Exposed to Human Immunodeficiency Virus

All infants born to a known HIV-infected mother or to a mother who falls into a high-risk category should be longitudinally evaluated for HIV infection. The routine diagnostic HIV tests employed in adults (enzyme-linked immunosorbent assay [ELISA] and Western blot) are based on the detection of anti-HIV antibodies, most of which are IgG. Because these routine HIV tests cannot distinguish infant-derived IgG from that transplacentally acquired from a seropositive mother, these tests virtually always are positive in the newborn period whether the offspring is infected or not and are of little usefulness.

The definitive diagnosis of HIV infection in a newborn requires the detection of virus or HIV-specific nucleic acid. Virtually all untreated newborns have HIV viral loads well above the level of detection, and this test is greater than 90% sensitive and virtually 100% specific by 4 weeks of age. Viral load assays further give an estimation of the severity of the infection and a baseline for judging the success of antiretroviral therapy. Some experts recommend testing the infant with a nucleic acid detection assay or by viral culture on three separate occasions up to 6 months of life. Infants who are repeatedly negative by that time no longer need to be followed for the possibility of HIV infection. Infants who test positive should have a second, confirmatory test performed before the diagnosis is established.

The CDC recommends initiating antiretroviral therapy for any infant diagnosed with HIV infection before age 12 months. Extrapolating from the experience with adults, such therapy should include at least three drugs derived from the nucleoside and non-nucleoside reverse transcriptase inhibitor families and the protease inhibitor family. Published experience with many of these agents in young infants is small relative to information available in adults, but preliminary results suggest that children have poorer virologic responses to multidrug regimens compared with adults. The treatment of infants with multidrug regimens poses difficulties not encountered in older patients, including devising dosing schedules that can be followed by frequently ill mothers and timing the administration of medication around feeds that may interfere with or increase the drug's bioavailability, depending on the agent. Proper use of these complex and potentially toxic agents requires the advice of an expert with substantial experience in perinatal HIV infection.

In addition to 6 weeks of prophylactic zidovudine, as outlined earlier, care of HIV-exposed infants requires few additional interventions. Because *P. jiroveci* pneumonia is the major life-threatening complication during the first year of the HIV-infected infant's life, many experts recommend that prophylaxis for *P. jiroveci* pneumonia should be administered beginning at 4 to 6 weeks and continuing for at least 1 year, or until HIV infection can be definitively excluded. The most effective prophylactic regimen is trimethoprim-sulfamethoxazole, 75 mg/m^2 per dose, twice a day, 3 days a week. The immunization schedule for HIV-infected infants is identical to immunocompetent infants, including recombinant hepatitis B vaccine at birth.

PROGNOSIS

Before the introduction of HAART, the median survival of HIV-infected children in the United States and Europe was 8 to 13 years. In the absence of antiretroviral therapy, rapid progressors usually have multiple, life-threatening complications and die early in life. A few perinatally infected children have reached adolescence and remain symptom-free with their immune systems intact even without antiviral chemotherapy. The ultimate outcome of these unusual cases is unknown. As in adults, the survival of children in industrialized countries has markedly improved since the introduction of HAART, reflecting the benefits of HAART regimens seen in adults. Longitudinal studies conducted in the late 1990s, the period during which HAART became standard in adults and children, documented a dramatic decline in yearly mortality among HIV-infected children. The reduction in mortality was experienced by all subgroups defined by age, sex, CD4+ T lymphocyte counts, and ethnicity.

ENTEROVIRUSES AND PARECHOVIRUSES

Enteroviruses belong to the family Picornaviridae. The four traditional groups of enteroviruses are the polioviruses, echoviruses, coxsackieviruses, and enteroviruses. Among these four groups, presently 67 serotypes are recognized. Although these groupings are still widely employed, more recent molecular analyses have categorized enteroviruses into five genetically defined species, and have indicated that some of the original members belong to nonenterovirus genera altogether. In particular, hepatitis A, initially designated an enterovirus, has been reclassified as a distinct and unique genus. Two additional former enteroviruses, echovirus 22 and 23, are sufficiently genetically and structurally different from the other enteroviruses to be assigned to a new genus name, *Parechovirus*. Several new parechoviruses have been identified.

Epidemiology and Transmission

Humans are the true hosts for the enteroviruses, but these viruses have been described in various animals, probably secondary to contamination from humans. They are transmitted primarily by the fecal-oral route, but they have also been transmitted by the oral-oral route and have been isolated in swimming pools, from contaminated hands, and from flies. Typically, within a given geographically defined population, a narrow range of serotypes is responsible for most endemic disease. The community incidence of enteroviral disease peaks in temperate areas in summer and fall, but occurs throughout the year in tropical areas. In addition to geographically confined organisms, occasional strains cause epidemics that can reach worldwide proportions. In all four enterovirus groups, there are far more subclinical, undiagnosed infections than recognized disease, but when disease occurs, it is particularly severe in the neonatal period.

Perinatal infection can occur before, during, or after parturition. Enteroviruses may be transmitted transplacentally, presumably during maternal viremia, and congenital infections have been most often described after a maternal infection in the third trimester; such infections can result in fetal death. Most infection in the neonatal period is the result, however, of exposure of the oral or respiratory tract mucosa to organisms harbored by the mother at the time of birth or from secretions from the mother or other humans shortly thereafter.

Epidemics of enteroviral disease have been described in the nursery. The virus may be introduced by personnel, but more commonly the infant index case has acquired the virus from his or her mother at the time of delivery. Risk factors for infection in the nursery include low birthweight, administration of antibiotics or blood, proximity to the index patient, care by the nurse of the index patient in the same nursing shift, and nasogastric feeding or intubation.

Infection during Pregnancy

Enterovirus infection during pregnancy is common, especially during peak periods of enteroviral disease in the community, with some surveys documenting an intragestational incidence of 9% or more. Few data indicate any risk from either the polioviruses or the echoviruses for the development of congenital anomalies, but the situation is less clear for coxsackieviruses. Early investigations found an association of coxsackieviruses A9 and B2 to B4 with a higher rate of anomalies, particularly urogenital and cardiovascular, but others have found no such association. Reports of prematurity and stillbirth exist for all the enteroviral groups after infection late in pregnancy, but these effects seem to be uncommon. In most pregnant women, the infection is either asymptomatic or associated with mild, nonspecific illness. By contrast, mothers infected with echoviruses or coxsackie B viruses, the enteroviral groups most commonly associated with significant illness in newborns, frequently complain of fever and abdominal pain near the time of delivery.

Neonatal Infection

The nonpolio enteroviruses cause a wide spectrum of illnesses, and substantial data have been collected regarding specific types and strains. The severity of disease in a newborn is a function of the infecting strain, the titer of passively transferred specific antibody in the infant, and the timing of infection. Maternal infection just before delivery, before the mother can mount an antibody response, with high-titer viral transmission immediately before or during birth is associated with the most severe symptoms in the newborn.

Most neonatal enteroviral disease manifests as a nonspecific mild febrile illness. These infections probably are acquired postnatally. Signs and symptoms occur between the first and second week of life, usually after the infant has been discharged from the nursery, and consist of fever of 38°C to 39°C, irritability, vomiting or diarrhea, and poor feeding. These infants frequently are admitted to the hospital for a bacterial sepsis evaluation and discharged 3 days later when the bacterial cultures have proved negative, and the infant's symptoms have spontaneously improved. Occasional infants exhibit respiratory distress, rash, or aseptic meningitis. The course is self-limiting, and recovery without residual is the rule.[84] A history of an intercurrent viral-like illness in a family member can usually be elicited. Nosocomial infection, acquired horizontally after birth, also frequently has this relatively mild course.

A more fulminant, life-threatening illness occurs as a consequence of vertical transmission at the time of birth but before the development of significant serotype-specific antibodies in the mother. The mortality is highest for echovirus-11, but other serotypes, particularly some coxsackie B viruses and several parechoviruses, also have been implicated.[65,151] Approximately one third to one half of infants with severe enteroviral disease are born prematurely.[1] In fulminant cases, onset of illness typically occurs within the first 2 to 5 days of life. Severe neonatal disease shares many characteristics of overwhelming bacterial infection, with extreme lethargy and hypoperfusion. Infants also present with fever, which may be greater than 39°C, poor feeding, and rash. The rash is usually macular or maculopapular, sometimes with petechiae. The most fulminant cases are complicated by hepatitis, first manifested by hepatomegaly and jaundice. Such cases can progress to necrosis of the liver and fulminant hepatic failure with intractable coagulopathy and hemorrhage, and profound hepatocellular dysfunction. Mortality from enteroviral hepatitis and coagulopathy ranges from 30% to 80%.[1]

Despite the life-threatening nature of the acute hepatic failure, recovery of hepatic function among survivors is the rule. Coincident with hepatitis, or sometimes separate from it, a newborn may have myocarditis, characterized by respiratory distress, tachycardia, and arrhythmias, with mortality approaching 50%. As with hepatitis, if the infant survives acutely, full recovery over a long course is usual. Both of these severe manifestations may occur coincidentally with meningoencephalitis. In these infants, the CSF examination often is typical for viral CNS disease, but some serotypes produce CSF changes typical of bacterial meningitis, including marked hypoglycorrhachia, and still others result in no CSF pleocytosis at all. Although there are a few reports of neurologic sequelae among survivors of aseptic meningitis, nearly all children develop normally. In contrast, neonatal encephalitis resulting from parechovirus may be severe, causing white matter injury and long-term sequelae in a significant proportion of affected infants.[150]

Enteroviral infection shortly after birth also has been implicated in a few cases of sudden infant death. Some infants have died within the first week of life. Mild prodromal symptoms usually precede the infant's death. Evidence of enterovirus has been found in the heart and respiratory tract at postmortem examination.

Laboratory Diagnosis

Traditionally, the diagnosis of enteroviral infection has been established by isolation of the virus in culture. Some serotypes of enterovirus are very difficult to grow in vitro, however. More recently, commercially available PCR technology has become available for enterovirus diagnosis, using primers that flank a highly conserved region in the 5′ noncoding region of the genome present in nearly all serotypes. When applied to infection in newborns and young infants, PCR diagnosis is more sensitive and much more rapid than viral culture. The widely used enteroviral PCR tests do not detect parechoviruses, however. Enterovirus can be identified by culture and PCR in serum, urine, CSF, nasopharynx, and stool. The usefulness of serology and antigen detection for diagnosis of enteroviral disease is precluded by the large number of non–cross-reacting serotypes.

Therapy and Prevention

The most important measure in limiting the spread of enteroviral disease is strict hand washing. Access to the nursery should be limited to healthy personnel. Cohort nursing care during nursery epidemics may be effective in limiting spread. There is some evidence that passive immunization with immune globulin during a nursery outbreak may be beneficial in limiting new cases and decreasing the severity of illness in affected infants.

High-dose intravenous immune globulin has been used in established neonatal disease, although there have been no controlled trials testing its effectiveness. Passive immunization has been shown to have a virologic effect in the infant only if the lot of immune globulin possesses very high titers against the offending serotype. The antiviral drug pleconaril is promising in neonatal enteroviral infection, but remains in development. This compound binds to sites on the enteroviral surface, prohibiting attachment to the target cell and subsequent uncoating. It has activity against numerous enteroviruses in vitro at concentrations that are readily achieved in the serum with human dosing. Preliminary experience, including data collected in neonates, indicates that the drug is highly bioavailable, has a large volume of distribution (including the CNS) and long half-life, and possesses few side effects. There have been numerous reports of pleconaril administration in infants with severe enteroviral disease, with recovery frequently occurring soon after drug initiation. Randomized trials in neonatal infection have not been published, however, and in the absence of controlled studies, the effectiveness of pleconaril in severe newborn enteroviral disease remains uncertain.

HEPATITIS VIRUSES

Hepatitis may result from various viral infections, including CMV, herpesvirus, rubella virus, EBV, VZV, and coxsackievirus. The disease usually occurs as part of a systemic infection. A primary infection of the liver, resulting in acute or chronic hepatitis, or both, may also be caused by specific hepatotropic viruses, as discussed in the following sections. (See also Chapter 48.)

Hepatitis A Virus

Hepatitis A virus (HAV) is a spherical, single-stranded, positive-sense RNA particle in the picornavirus group. HAV is distributed worldwide. The infection is highly contagious and is spread most commonly by the fecal-oral route. Common source outbreaks resulting from contaminated food, particularly raw shellfish culled from tainted waters, also occur. Rarely, HAV is transmitted by blood transfusion or from mother to child. Fecal excretion of HAV begins 2 to 3 weeks before onset of the disease and may continue for 4 to 6 weeks. The average incubation period is 25 to 30 days.

HAV is a common infection in children, and children in daycare are at particular risk. Most pediatric infections are asymptomatic and anicteric. Children who do exhibit symptoms usually have a gastroenteritis-like syndrome and experience only mild hepatitis with virtually complete resolution. Adults are more likely to develop the typical signs and symptoms of hepatitis, with jaundice, abdominal pain, malaise, fever, acholic stools, dark urine, and vomiting. Fulminant disease is uncommon, and the mortality is less than 1%. The carrier state does not occur. The diagnosis is made by detecting anti-HAV IgM antibodies in the serum, which appear with the onset of disease and persist for several months. Detection of anti-HAV IgG, which persists throughout life, may indicate either recent or distant infection.

Acute HAV in pregnancy does not seem to increase the risk of congenital malformations, stillbirths, intrauterine growth restriction, or spontaneous abortion. The risk of perinatal transmission is minimal, even when the mother develops acute disease within the last weeks of pregnancy.[144] Perinatal transmission can rarely occur, however, and spread in special care nurseries has been reported. In most instances, neonatal disease is asymptomatic or mild and is self-limiting. Occasional reports suggest that maternal disease with HAV during pregnancy can result in meconium peritonitis in the fetus.

Although vertical transmission of HAV is unusual, some authorities recommend treating the infant with 0.02 mL/kg of immune serum globulin intramuscularly if maternal symptoms develop 2 weeks before to 1 week after delivery. The unusual nursery outbreak of HAV should be managed with the administration of prophylactic immune globulin to susceptible staff and infants and with emphasis on good hand washing. Two formalin-inactivated HAV vaccines are available in the United States and are highly protective, but are not yet licensed for children younger than 12 months of age.

Hepatitis B Virus

Hepatitis B virus (HBV) is the prototype of the family of viruses known as *hepadnaviruses* (hepatotropic DNA viruses). The complete infectious virion is a 42-nm sphere. Hepatitis B surface antigen (HBsAg) is found in the viral envelope and is produced in excess during infection, resulting in circulating, free spherical and tubular particles. It is detected (usually by radioimmunoassay [RIA] or ELISA) in acute and chronic infection. Subdeterminants of the surface antigen define four major serotypes. All four share an epitope designated “a”; antibody to HBsAg (anti-HBsAg) is directed against this common epitope and confers some protection against all four serotypes.

The viral inner core nucleocapsid contains hepatitis B core antigen (HBcAg), DNA polymerase, and partially double-stranded DNA. HBcAg is expressed on the surface of the infected hepatocyte, but does not circulate and cannot be detected by routine assays. Anti-HBcAg, total and IgM specific, can be detected by RIA or ELISA. HBeAg, a soluble polypeptide encoded within the same open reading frame as the core antigen, is detectable when HBV replication is rapid. Its appearance usually indicates a high concentration of HBV. HBeAg-negative individuals are infectious, but transmission of disease occurs at a lower rate. HBeAg and anti-HBe also can be detected by either RIA or ELISA. Several genotypes of HBV have been defined and designated types A through H. HBV DNA initially is transcribed into RNA intermediates, which serve as messages for viral proteins or as a template for progeny viral genomic DNA through reverse transcription by the viral polymerase.

CLINICAL MANIFESTATIONS AND HEPATITIS B VIRUS BLOOD TESTS

HBV infection is most often contracted by injection drug use, but may be transmitted through intimate physical contact or vertically from mother to infant. Blood products are routinely screened for HBV, and transfusion, previously the most common source of HBV infection, is now only rarely implicated. The incubation period is 50 to 180 days. HBsAg usually is present 1 to 3 months after exposure and appears before the onset of symptoms. Elevation of hepatocellular enzymes in the serum may be found 2 weeks to 2 months after HBsAg is detected. This period in adults frequently is characterized by a prodrome of nausea, vomiting, headache, and malaise, which progresses to jaundice.

Within 1 to 2 weeks of the onset of jaundice, HBsAg usually is cleared from the serum. With self-limited disease, there is often a window period between the disappearance of HBsAg and the development of anti-HBsAg so that both tests are negative. The appearance of anti-HBsAg is a marker of recovery and immunity against future reinfection. The IgM antibody response to HBcAg begins before the disappearance of HBsAg and persists through the window period. Testing for HBsAg and IgM anti-HBcAg is the most reliable strategy to document recent HBV infection. IgM anti-HBcAg disappears by 6 months, but the later appearing IgG anti-HBcAg may persist for life. HBeAg is variably expressed in HBV disease and denotes actively replicating, high-titer infection. The development of anti-HBeAg signals improved control of viral replication, but not eradication. HBV vaccines are composed of recombinant HBsAg; recipients of vaccine are positive for anti-HBsAg. Vaccine recipients can be distinguished from hosts who have recovered from wild-type infection by the absence of antibody to other viral components, particularly anti-HBcAg.

Most HBV-infected adults have a self-limited disease and become noncontagious. Less than 1% develop fulminant hepatic failure, but many of these patients die. The virus is not cytopathic for the infected hepatocyte, and hepatic damage and subsequent viral clearance are the results of the host's immune response. Chronic active or persistent hepatitis, which may develop in 30% of chronic carriers, is characterized by persistent serum HBeAg in the absence of anti-HBsAg and is particularly common in patients superinfected with the hepatitis D virus.

Infants born to antigen-positive mothers or mothers with acute hepatitis have a 35% incidence of prematurity and are more likely to be of low birthweight. The risk of preterm birth seems to be related to degree of maternal illness. Fulminant fatal cases of neonatal hepatitis secondary to vertically transmitted HBV are uncommon, but do occur (1% to 2% of all cases) and may be recurrent in successive pregnancies. More typically, infants infected with HBV develop a less robust immune response to the HBV-infected hepatocyte compared with adults and establish asymptomatic chronic infection ("chronic carriage"). The development of chronic carriage is strongly correlated to age: 95% of infants become chronic carriers compared with 30% of toddlers and 5% of adults.[56]

The consequences of chronic HBV carriage established in the newborn are not encountered until early adulthood, at which time the patient has a gradual onset of hepatic fibrosis and insufficiency. Carriers also may develop hepatocellular carcinoma after the initial infection. Hepatocellular carcinoma is most common in populations affected by a high incidence of vertically transmitted HBV and in populations with high cross-sectional prevalence of HBV surface and HBe antigenemia.[140] HBV itself is not oncogenic; the formation of tumor is probably the result of years of low-grade inflammation and repeated hepatocellular regeneration.

PERINATAL TRANSMISSION

Multiple studies have shown that vertical transmission of HBV is strongly associated with high-grade maternal HBe antigenemia, and that almost all infants born to HBeAg-positive mothers are infected in the first year of life, with 85% to 90% developing chronic viral infection. The risk of vertical transmission of HBV from an asymptomatic carrier mother to her infant increases from 10% to 85% when the mother is HBeAg-positive. Mothers may transmit HBV vertically in sequential pregnancies. The risk of vertical transmission of HBsAg from mother to infant at birth is higher in Asia than in Western industrialized countries.

Transmission occurs significantly more often at birth or in the postpartum period than transplacentally. Cord blood samples frequently are HBsAg-negative in infants who subsequently become infected. Peripartum transmission is implied further by observations made in mothers who acquire acute hepatitis B infection during pregnancy. The risk is very low with infection during the first two trimesters, but increases to 50% to 75% with hepatitis late in pregnancy or in the early postpartum period. Entry of virus through the infant's gastrointestinal tract is suggested by the finding that 95% of the gastric contents of infants born to carrier mothers are HBsAg positive after birth.

Although HBsAg can be found in the breast milk of 70% of carrier mothers, studies have not shown an increased risk with breast feeding, indicating that mothers who desire to breastfeed may do so with little risk. American studies indicate further that breast feeding carries no detectable risk of vertical HBV transmission in an infant who has received appropriate immunoprophylaxis at birth.[53]

There is also risk of transmission of HBV to family contacts of HBsAg carriers from close contact over long periods. The risk is higher from sibling carriers than from either parent, and is increased when the family member has evidence of liver disease. In the developing world, a significant proportion of infant infection is the result of horizontal transmission from the mother or other family member during the child's early life, rather than infection at the time of birth.

PREVENTION

Approximately 0.8% of women in the United States are HBsAg-positive in pregnancy. Active and passive immunization can prevent vertical transmission of HBV in 85% to 95% of cases, even in high-risk situations. The institution of immunoprophylaxis has had a profound impact on the incidence of newborn-acquired acute and chronic HBV infection and the associated hepatocellular carcinoma, particularly among high-prevalence populations in the United States (e.g., Alaskan Natives) and in areas of high endemicity in the developing world.[24,79]

Less than 50% of HBV-infected women in the United States have risk factors for HBV infection. Consequently, present recommendations mandate routine, universal screening of all pregnant women for HBV and universal vaccination of all infants. Current guidelines recommend that all pregnant women be tested for the presence of HBsAg early in gestation. Women at high risk for acquiring HBV, such as intravenous drug users or women with clinical hepatitis, should be tested again shortly before parturition. Hospitals are advised to develop systems that ensure the results of HBV screening tests are available to the pediatrician at the time of delivery. In everyday practice, some women without identified risk may acquire infection after the initial screening test, and others fail to be rescreened, and it may be impossible to transmit every woman's HBV status to the pediatrician in a timely fashion. In large centers that can perform HBV testing daily, screening at the time of delivery may overcome both of these potential problems.

Treatment of the infant varies, depending on whether the mother is HBsAg-positive, HBsAg-negative, or of unknown status at delivery. Infants of HBsAg-negative mothers do not need treatment with hepatitis B immune globulin (HBIG). They should be vaccinated before leaving the hospital with either Recombivax HB (5 μg in 0.5 mL) or Engerix-B (10 μg in 0.5 mL). Both must be given intramuscularly. Subsequent doses should be given at 1 and 6 months of age, although the last dose may be given up to 18 months of age. Combination vaccines currently are available that include HBV antigen and other childhood vaccines in the same vial. Only the monovalent preparation of hepatitis B vaccine should be used for the first dose, however, assuming it is administered at less than 6 weeks of age.

Infants of HBsAg-positive mothers should be passively immunized with HBIG (0.5 mL given intramuscularly) and hepatitis B vaccine at a different anatomic site within 12 hours of birth, although some benefit can be realized even if given 48 hours after birth. The vaccination schedule should be completed by 6 months to ensure rapid protection of the infant. In contrast to infants born to HBsAg-negative mothers, infants born to HBV-infected mothers should be tested for HBsAg and anti-HBsAg after the vaccine schedule has been completed (at age 9 to 15 months, to allow clearance of HBIG from the infant's bloodstream), to detect failure of seroconversion or vertical transmission despite vaccination.

If the mother's serologic status is unknown, maternal HBsAg should be tested at delivery, and the first dose of the vaccine should be given to the infant within 12 hours of birth. If the mother proves to be positive for HBsAg, HBIG should be administered to the infant as soon as possible, but certainly within the first 7 days of life.

Early studies examining hepatitis B vaccine response in preterm infants indicated a lower seroconversion rate among infants with very low birthweight born to HBsAg-negative mothers compared with infants weighing more than 2000 g. Subsequent studies have determined that medically stable preterm infants immunized at 30 days of age have an antibody response similar to full-term infants regardless of gestational age or birthweight. In a preterm infant born to a mother who is HBsAg-negative, the first dose of HBV vaccine should be given at 30 days of life or when the infant reaches 2000 g, before hospital discharge. In preterm infants born to HBsAg-positive mothers, HBV vaccine should be given within 12 hours of birth (along with HBIG), but the full three-dose vaccine schedule should be initiated at 30 days of age (i.e., the infant should receive a total of four vaccine doses).

If a preterm infant is born to a mother with uncertain HBV status, and her status cannot be determined within 12 hours after delivery, HBIG should be administered to the infant immediately because the suboptimal immune response to vaccine alone precludes its use as a single intervention in the event that the mother proves to be HBV-positive. If the mother's HBV tests ultimately show she is negative for virus, the vaccine schedule can proceed using the same schedule for mothers known to be HBsAg-negative at delivery.

After nearly 20 years of widespread newborn vaccination, the hepatitis B vaccine seems to be exceedingly safe when given during infancy.[82] The original hepatitis B vaccine preparations contained the preservative thimerosal, a derivative of mercury. Concerns regarding the potential, albeit unproven, toxicity of thimerosal prompted a brief suspension of perinatal hepatitis B vaccination in the late 1990s and a mandate to develop vaccine formulations that did not contain this preservative. By 2001, all vaccines included in the childhood schedules were either thimerosal-free (including hepatitis B) or contained only trace amounts.

Hepatitis C Virus

Hepatitis C virus (HCV) is a single-stranded RNA virus of the family Flaviviridae. HCV is composed of six genotypes and multiple subtypes. The severity of the infection corresponds to the HCV strain, with genotype 1 producing the most aggressive course. HCV is the most common chronic bloodborne infection in the United States, and the most frequent condition requiring liver transplantation. The seroprevalence among volunteer blood donors in the United States is approximately 1% to 2%. At present, intravenous drug use is the most prominent risk factor for acquisition of HCV. Health care workers experiencing a needle-stick injury or mucous membrane exposure to blood products also are at risk. Sexual transmission of HCV is uncommon, and household contact results in viral transmission only rarely, if at all.

Historically, transmission occurred most frequently after exposure to blood or blood products, including sporadic lots of intravenous immune globulin. The practice of administering multiple small-volume transfusions to ill neonates during the 1960s and 1970s resulted in inadvertent HCV infection in a substantial proportion of the recipients. The screening of potential blood donors with newer generation antibody tests for HCV has greatly reduced the incidence, however, of transfusion-acquired infection in adults and children. Since the implementation of these screening programs, vertical transmission has become the most common mechanism of HCV infection in children.

HCV infection has a 30- to 60-day incubation period. In unusual circumstances, infection results in acute hepatitis with symptoms similar to those caused by other hepatotropic viruses—abdominal pain, jaundice, nausea, vomiting, fever, and malaise. Most acute infections in adults are asymptomatic, however. More than half of all HCV-infected adults develop chronic hepatitis, which may resolve or may progress in one fourth of patients to cirrhosis and eventually to hepatic failure.[124] As with chronic HBV infection, chronic HCV infection is a significant risk factor for hepatocellular carcinoma. Interferon-α therapy has been successful in generating long-term remission in some patients with chronic HCV infection, but the relapse rate is high. Concomitant ribavirin improves the response. Therapy is otherwise supportive.

Although HCV infection is relatively prevalent among young adults, almost every expert recommends against screening for HCV during pregnancy, unless the woman possesses known risk factors for infection, such as transfusion or organ transplantation before 1992 or infusion of clotting factor concentrates before 1987; intravenous drug abuse; presence of a tattoo or body piercing that was placed unprofessionally; or HIV infection. Pregnancy does not seem to worsen the severity of HCV infection, and HCV infection does not seem to increase maternal or fetal morbidity and mortality beyond that conferred by concomitant maternal drug use. As in nonpregnant adults, most pregnant women infected with HCV are asymptomatic with only mildly abnormal liver function tests. Interferon and ribavirin are contraindicated in pregnancy, and if therapy is indicated, it should be deferred until after delivery.

The incidence of mother-to-child transmission in women not coinfected with HIV is approximately 5%.[90] HIV coinfection in the mother increases the risk of vertical transmission of HCV twofold to fivefold. More recent data suggest, however, that effective multidrug therapies for HIV during pregnancy may reduce the risk of transmission of HCV as well. Maternal illicit drug use also increases the risk of vertical transmission of HCV to the newborn. Transmission seems to be a function of the degree of maternal viremia. If the mother's serum is HCV-negative by PCR, the rate of transmission to the newborn approaches zero.[36] Conversely, studies have indicated that transmission rates are roughly proportionate to maternal HCV plasma load.[59] No minimal level of viremia has been established below which the infant is safe, however.

Most infants probably are infected at or near delivery, and several investigators have documented that the risk of vertical transmission is increased by prolonged rupture of the membranes and invasive fetal monitoring, both of which heighten the exposure of the newborn to maternal blood.[90] Most series have been unable to document protection from HCV vertical transmission by cesarean section.[59] Some samples of colostrum and breast milk contain detectable HCV RNA, but studies indicate no increased risk of mother-to-child transmission attributable to breast feeding as long as the nipples are not damaged or bleeding.[141] Administration of immune globulin to a newborn has no role in preventing vertical transmission because donors for commercial immune globulin preparations are screened and rejected for the presence of HCV antibodies.

Infants born to mothers infected with HCV are virtually all asymptomatic at birth and remain so for years.[145] There are few long-term longitudinal studies of these infants. Progression of disease seems to be slower in children than in adults, and most children experience only mild to moderate intermittent elevations of serum liver transaminase levels through at least the first two decades of life. Liver histologic changes tend to be mild as well. It is uncertain how many of these children progress to cirrhosis or hepatocellular carcinoma later in life. A small proportion of children with vertically transmitted HCV clear the infection spontaneously over their first few years. Maternal HCV antibodies may be detectable in the infant for 18 months and cannot be used for diagnosis unless they persist beyond this time. HCV-specific RNA can be detected in the serum by PCR. Most infants born to a mother infected with HCV have negative HCV PCR at birth, but, if infected, PCR becomes positive after the first 1 or 2 months. Thereafter, the test is variably positive throughout life, reflecting intermittent episodes of viremia.

Hepatitis D Virus

Hepatitis D virus (HDV), formerly known as the δ agent, is a defective RNA virus that uses HBsAg as its surface coat and requires coinfection with HBV. Its epidemiology is the same as HBV. HDV is transmitted parenterally, and in the United States is most commonly found in drug addicts and hemophiliacs. HDV is worldwide in distribution. Perinatal transmission, which is rare, occurs only with HBV transmission and can be interrupted by interrupting HBV perinatal transmission.

Hepatitis E Virus

Hepatitis E virus (HEV) is a single-stranded, positive-sensed, nonenveloped RNA virus unrelated to the other hepatitis agents. HEV disease has been identified in Asia, Africa, the Middle East, and Central America.[136] Occasionally, a case is diagnosed in an immigrant in the United States or Europe. In endemic areas, HEV occurs sporadically, but several instances of large outbreaks have been reported, typically affecting thousands of people. Infection is transmitted through contaminated water supplies sullied by sewage; person-to-person spread is uncommon. The diagnosis can be made by identification of viral particles in the stool, by Western blot assays for anti-HEV IgM and IgG, and by detection of circulating viral RNA using PCR, but these tests are not routinely available in most hospitals in the United States. In nonpregnant adults, infection with HEV is similar to that caused by HAV. Most cases are characterized by self-limiting icteric hepatitis with full recovery. Subclinical and anicteric infections also occur. Fulminant hepatitis results from a small fraction of infections. HEV infection does not lead to chronic hepatitis.

There is a striking association between pregnancy and the development of overwhelming HEV-related hepatitis, particularly in women from the Asian subcontinent. In some endemic areas, HEV is the most common identifiable cause of clinically apparent hepatitis in pregnant women, even when the prevalence of HEV in the general population is lower than other hepatotropic pathogens. Massive hepatic necrosis is particularly prominent during the third trimester of pregnancy, when the mortality rate can exceed 20%.[3] The reasons for this predilection are unknown, but some data suggest that hormonal elevations during pregnancy promote viral replication.[63]

Mild HEV disease during pregnancy can result in abortion, intrauterine death, stillbirth, or preterm delivery.[112] Reports studying a few subjects have documented vertical transmission of HEV in more than half of infants born to mothers who were viremic during pregnancy. Blood-borne virus can be detected soon after birth, suggesting intrauterine transmission. All the affected infants had abnormalities of liver function tests, and approximately 20% to 25% died; one of these had hepatic necrosis at autopsy. Liver function returned to normal in survivors after 2 to 3 months.

Hepatitis G Virus and GB Virus Type C

Hepatitis G virus (HGV) and GB virus type C (GBV-C) were isolated independently, but subsequently proved to be nearly identical flaviviruses based on genetic sequence. HGV/GBV-C has a genomic organization similar to HCV. In adults, infection by HGV/GBV-C results in viremia that lasts for months to years, but the virus eventually is cleared by the appearance of antibody against the viral protein E2. Although initial studies suggested that HGV/GBV-C was a cause of hepatitis, subsequent surveys have failed to establish that HGV/GBV-C infection produces liver disease or any disease at all. This observation, along with data that suggest HGV/GBV-C primarily infects lymphocytes rather than hepatocytes, has prompted some experts to recommend that the name "hepatitis G virus" be discontinued.

HGV/GBV-C is transmitted through the same routes as HIV and HCV—transfusion, injection drug use, sexual activity, and vertical transmission from mother to infant. Occasional patients with HGV/GBV-C infection have none of these risk factors, suggesting that other modes of acquisition occur as well. Prevalence studies have documented that active infection, defined by the detection of circulating HGV/GBV-C RNA, and past infection, defined by the presence of antibody to HGV/GBV-C, are extraordinarily common in healthy individuals and patients with underlying conditions. Approximately 2% of blood donors have evidence of active HGV/GBV-C infection, and an additional 15% to 18% have evidence of past infection. Coinfection with HGV/GBV-C occurs in more than 20% of subjects with HCV infection. Ongoing or past infection by HGV/GBV-C is detected in two thirds or more of intravenous drug users and patients with HIV. Although no clinically apparent disease has been identified in individuals infected with HGV/GBV-C, interest in this virus has been rejuvenated by studies suggesting that active HGV/GBV-C replication in HIV-infected patients may slow the progression of HIV disease. The mechanism of this putative protective effect in HIV-infected hosts is uncertain.

HGV/GBV-C is efficiently transmitted from mother to child. Studies that have included healthy women and mothers coinfected with HCV or HIV have documented HGV/GBV-C transmission to more than half of their offspring. Typically, an infant becomes positive for HGV/GBV-C RNA by 3 months of age, and, similar to adults, active infection lasts for months. Most studies have failed to detect an independent association between HGV/GBV-C infection in vertically infected newborns and subclinical or clinically apparent liver disease. To date, no other clinical consequences have been identified in infected infants.[156]

ROTAVIRUS

Rotavirus is the predominant cause of acute viral gastroenteritis in infants and young children. It is a double-stranded RNA virus containing 11 genomic segments. The virus is composed of three concentric capsid shells. Strains are characterized by the electrophoresis migration patterns of the RNA segments and by structural differences of the capsid proteins VP6, VP7, and VP4. VP6 serotype A accounts for most of the rotaviruses that are pathogenic in humans. The virus replicates primarily in enterocytes in the proximal small intestine, where infection leads to denuding of the villus tips and mononuclear cell infiltration of the underlying lamina propria. The virus seems to remain localized to the intestine. It has not been identified in breast milk.

Epidemiology and Transmission

The distribution of rotavirus is widespread throughout the industrialized and developing world. The virus causes an estimated 150 million diarrheal episodes in infants and young children each year, and approximately 0.5 million deaths. Rotavirus infections are usually prevalent in temperate climates during the winter months, whereas in tropical areas, infection is endemic year-round. In some nurseries, endemic infection rates reflect the incidence in the community, but in others the incidence of disease is relatively constant. Rotavirus infection in neonatal units may also occur in the context of a clinically apparent outbreak. The distinction between endemic and epidemic rotavirus disease is blurred, however, in the nursery. Longitudinal prevalence surveys conducted in geographically diverse nurseries during periods without outbreaks indicate that 10% to 70% of infants admitted for more than 1 week excrete rotavirus at some time before discharge, often asymptomatically, and that typically only one or two strains account for all the infections over many months.

Epidemiologic aspects of rotavirus potentiate its spread in a confined environment, such as a nursery. The stool of infected individuals contains high titers of virus, and infection can be transmitted by very small inocula. Additionally, the virus survives on inanimate surfaces and is resistant to many commercial disinfectants. Rotavirus likely is introduced into the unit by a newborn who acquires infection during delivery after exposure to maternal stool, or by an infant or a staff member who imports the virus from the community. Thereafter, most infection is nosocomial, transmitted via the hands of personnel. Viral excretion in the stool begins 1 to 2 days before the onset of diarrhea, is highest after 3 to 4 days of diarrhea, then wanes 1 to 2 weeks later. Outbreaks may spread rapidly through the nursery, where the most important factors determining spread seem to be the frequency of handling the infants and the closeness of the bed spaces.

Clinical Manifestations

Nearly all reports indicate that rotavirus infection frequently is asymptomatic or mildly symptomatic in newborns. Some data suggest that maternally derived serum and intestinal antibodies and possibly breast milk antibodies may be responsible for preventing or ameliorating infection early in life. Additionally, a high proportion of nursery infections are caused by the VP4-serotype designated *P[6]*.[85] This serotype is not usually isolated from older children with community-acquired symptomatic infection. The reasons underlying the predilection of newborns for P[6] strains are unknown, but this observation suggests that the relatively mild disease in infants may partially be the result of intrinsic properties of the infecting virus.

Symptomatic infants develop irritability and poor feeding, followed by watery or mucous stools that are sometimes bloody and frequently contain increased reducing substances.[120] Occasionally, infants develop severe diarrhea and dehydration, but fatalities are rare. There has been speculation that rotaviral infection may predispose to necrotizing enterocolitis, but such an association has not been clearly established.

The diagnosis is usually made by detection of viral antigen in stools using ELISA. False-positive results may be 1% to 4%. Hand washing remains the most effective prophylactic measure. Hard surfaces should be washed with alcohol-containing disinfectants because quaternary ammonia-containing compounds are not active against the virus. Therapy consists of rehydration and maintenance of fluids and electrolytes. Some investigators have found that breast feeding prevents infection or lessens the severity of the illness.

A tetravalent vaccine approved by the FDA in 1998 was removed from the market in 1999 because postmarketing surveillance indicated a rare association with intussusception. Two additional oral rotavirus vaccines were introduced in the mid-2000s: a pentavalent product composed of five reassorted strains derived from human and bovine rotaviruses, and a monovalent vaccine composed of an attenuated human strain. Both vaccines seem to be protective and free of significant side effects, including intussusception. The first dose of each vaccine is preferentially administered at 2 months, although both may be given at 6 weeks. Immunization of preterm neonates is recommended at the same postnatal age if the infant is otherwise stable, and he or she has been discharged from the hospital.

PARVOVIRUS B19

Parvoviruses are small (23 to 25 nm), single-stranded DNA viruses of the family Parvoviridae (genus *Erythrovirus*) that lack an envelope, but form capsids. (*Parvum* is the Latin word meaning "small.") The viral genome consists of approximately 5600 nucleotides and encodes for only three proteins—a nonstructural protein, NS1, which functions in replication and is responsible for the destruction of the erythroid progenitors, and two structural proteins, viral protein 1 (VP1) and viral protein 2 (VP2).[163] VP1 differs from VP2 only in that it has 226 additional amino acids at its amino terminal. Although most of the capsid consists of VP2, which may assist in the entry of the virus into the cell, the additional 226 amino acids of VP1 form loops that are external to the capsid and contain the epitopes recognized by neutralizing antibodies. Immunity to parvovirus occurs primarily through the antibody response, and IgG confers lasting immunity.

Parvoviruses are animal viruses, which seem to be species-specific. Parvovirus B19 replicates only in human erythroid precursors and is the only virus in the family definitely known to be pathogenic in humans. Parvovirus B19 was identified in 1975 in the sera of blood being screened for hepatitis B, and its name signifies the well in which it was identified. Parvovirus B19 is distributed worldwide, and infection occurs sporadically throughout the year, although there are seasonal increases in temperate zones, particularly in the spring, and epidemics occur every 4 years.

Transmission of infection occurs mainly through contact with respiratory secretions or droplets, but also occurs vertically from mother to fetus and via blood or blood products. IgG antibodies to parvovirus B19 are believed to confer lifelong immunity, and vertical transmission has not been documented in women with immunity before pregnancy. Secondary infection rates among nonimmune household contacts approach 50%, and childcare personnel and teachers have an occupational risk of approximately 20%. Although seroprevalence is found in only 5% to 10% of young children, it increases to approximately 50% in young adults and is nearly 90% in elderly adults. The annual seroconversion rate of women of childbearing age is estimated to be 1.5%. The risk seems to be greatest in homes with multiple children, especially between ages 3 and 10 years. The incubation period usually is 4 to 14 days, but can be 21 days. Rash and joint symptoms appear 2 to 3 weeks after infection. Individuals are most infectious before the onset of the rash, but are no longer so after the appearance of the rash, so school attendance with rash is not of concern. Hospitalized patients with aplastic crisis may remain contagious for a week after the onset of symptoms.

Clinical Manifestations

In most instances, infection with parvovirus B19 is asymptomatic and remains unrecognized. The most common illness is erythema infectiosum, or fifth disease. These individuals usually have a syndrome of malaise and low-grade fever, followed by the development of an erythematous, "slapped cheek" rash, sparing the nasal bridge and circumoral region, and a blotchy, maculopapular rash of the trunk and extremities. These areas develop central clearing, resulting in a reticular pattern. This rash may recur with heat or cold exposure. Individuals shed virus during the prodrome and are unlikely to be infectious by the time the rash aspect of the illness occurs. Another manifestation that is less common in children is a symmetric arthralgia or arthritis, particularly of the hands, wrists, and knees, which is usually self-limited. Both manifestations, rash and arthropathy, seem to be immune mediated.

Because the virus causes lysis of red blood cell precursors, it may cause a transient red blood cell aplasia, which is rarely significant in healthy individuals. Aplastic crises may result, however, in the presence of hematopoietic disease, such as sickle cell disease or thalassemia. Chronic infection and anemia may result in patients with immunodeficiency disorders. Other reports suggest an association of the virus with myocarditis,[110] peripheral nerve abnormalities, or vasculitis.

Fetal Infection

Fifty percent of pregnant women are susceptible to parvovirus. When infection occurs, transplacental transmission of parvovirus is estimated to be 30% to 50%; fetal loss occurs in 5% to 9% of the fetuses.[118] Most pregnancies result in apparently normal newborns despite proven fetal infection,[74] although there may be an increase in infants who are small for gestational age and spontaneous abortion. Although there have been a few reports of congenital anomalies, the relationship to parvovirus infection is not yet proven. In studies of viral causes of intrauterine fetal deaths, parvovirus was found in 13% of fetuses and was highly associated with chronic villitis and hydrops fetalis.[139] Parvovirus B19 attaches to the globoside glycolipid cellular receptor found on erythroid precursor cells (erythroblasts and megakaryocytes), erythrocytes, placental syncytiotrophoblast, fetal myocardium, and endothelial cells, but replication occurs only in the erythroid progenitor cells.[163]

The most common adverse fetal outcome reported in infected fetuses is hydrops fetalis; parvovirus B19 may be responsible for 20% to 30% of the cases of nonimmune hydrops, particularly during epidemics. The virus infects the erythroid progenitor cells in the fetal liver, causing a maturation arrest at a time that the fetus is expanding its red blood cell volume and has a shortened red blood cell life span, resulting in severe fetal anemia in most, but not all, instances. Fetal anemia results in congestive heart failure, a known cause of hydropic changes, such as generalized edema, ascites, and pleural effusions.

The virus may also cause myocarditis, after attachment to the globoside receptors in the myocardial cell, which also results in hydrops. Some fetuses develop thrombocytopenia and hepatic damage. Meconium peritonitis has resulted from small bowel obstruction and perforation. Placental damage, resulting in leakage of α-fetoprotein, is often linked to poor outcome. The risk of hydrops is greatest between 17 and 24 weeks of gestation, when fetal red blood cell precursors are developing, but hydrops may occur in the third trimester as well. Of fetuses with hydrops who received no treatment, half resolved spontaneously, and one third resulted in fetal death. Fetal death usually occurs 3 to 5 weeks after the maternal illness, but may occur 11 weeks later. The mother may also become ill with "mirror syndrome," which consists of a preeclampsia-like state, with anemia, hypertension, proteinuria, and swollen legs, mirroring the fetal infection.[31]

There are too few cases of hydrops secondary to parvovirus B19 to conduct a controlled trial, so most clinicians advocate intrauterine transfusion. Measurement of the middle cerebral artery peak systolic velocity on fetal ultrasound may be useful as an indicator of the need for fetal transfusion. When transfusion has been used, survival of the fetus has been 85%. One fetus with hydrops was also successfully treated with intrauterine fetal peritoneal injection of parvovirus B19 hyperimmune gammaglobulin.[91] Fetuses who survived intrauterine transfusion had a good neurodevelopmental outcome on follow-up.[32] Serial ultrasound studies and serum α-fetoprotein screening may be beneficial, but are unproven. Digitalization has also been used for fetuses with myocarditis. Surviving fetuses do not seem to have heart disease. A few cases have also been reported of encephalitis, meningitis, perivascular calcifications, and intrauterine stroke. In these cases, virus seems to infect the immature endothelial cells.

Diagnosis

Because parvovirus B19 is too fastidious to grow in the laboratory, serology remains the best means of diagnosis, with the measurement of specific IgM or an increase in titer of specific IgG. IgM antibodies appear 7 to 14 days after infection and are often present for at least 6 months. IgG antibodies appear within days and persist for the life of the patient. Not all fetuses make parvovirus B19 IgM, so viral DNA needs to be detected. Parvovirus B19 DNA may be detected in maternal serum, amniotic fluid, or fetal blood using PCR, but the presence of the antigen does not always indicate recent infection because a tiny percentage of healthy individuals can also have parvovirus B19 antigen isolated from their blood. Placental infection has been documented at 14 to 16 weeks' gestation, but it is rare for the amniotic fluid to be infected before 21 weeks of gestation, and detection of amniotic fluid infection usually requires a delay of at least several weeks after the maternal infection. Placental infection does not invariably result in fetal infection.

Isolation

Contact isolation with gown, gloves, and mask is indicated for hospitalized patients with aplastic crisis. Pregnant health care personnel should be aware of their risks, although the magnitude of this risk is uncertain. Serologic testing and the option not to care for a patient with an aplastic crisis may be offered. Patients with only the rash of erythema infectiosum are not contagious. A vaccine has been developed, but is unavailable, and the cost-effectiveness is questionable.

INFLUENZA A AND B

The influenza viruses are RNA viruses of the Orthomyxoviridae family. Although there are three antigenic types (A through C), type C has not played a significant role in neonatal infections and is associated primarily with coryza. Type B is responsible for about 10% of infections in humans, but is not usually associated with epidemics. Type A virus is also classified by the presence of two distinct glycoprotein surface antigens, the hemagglutinin and neuraminidase antigens. Hemagglutinin is responsible for viral binding to cell receptors, and neuraminidase is responsible for the release of virus after replication from the cell.[161] The H1, H2, and H3 hemagglutinin subtypes, and the N1 and N2 neuraminidase subtypes are particularly important in epidemics because immunity is largely due to the production of antibody to these antigens, and "drifts," or minor changes in the antigens, occur over time, requiring changes in the immune response to the virus.

An antigenic "shift," with the development of a new hemagglutinin or neuraminidase antigen, results in pandemic infection at infrequent intervals. In one 10-year study among

209 infants in the first year of life, influenza A (H3N2) occurred most commonly, followed by influenza B and influenza A (H1N1), with infections in 178, 96, and 26 infants.[44] More recent epidemics of avian H5N1 influenza A in humans have resulted from direct contact with birds. Disease has been particularly severe in infants and young children. There has been increasing concern that the genome of avian H5N1 influenza A could mix with human influenza A and be able to be transmitted directly from human to human and be able to cause widespread disease.

Influenza is rapidly and easily spread person to person by aerosol droplet or by contact with contaminated secretions. Viral shedding and infectiousness are greatest in the 24 hours before onset of symptoms and at the peak of symptoms. The virus may survive in the environment, although the role of fomites in transmitting infection is unclear. The incubation period is 1 to 3 days. Winter outbreaks are more common in temperate climates. School-age children have the highest attack rate and serve as a source of spread to adults and younger children. Hand washing and cohorting are the most effective means to interrupt epidemics within the NICU. Cohorting requires rapid diagnosis. PCR detection of influenza RNA is the most rapid and sensitive means of diagnosis. In addition, staff members should not work when ill, and family members should be carefully screened, particularly in season, for viral illness before admission to the NICU.

All women who may be pregnant during an influenza season should receive inactivated vaccine. The vaccine is safe throughout pregnancy and breast feeding.[161] Staff members in the NICU should also be encouraged to be vaccinated; compliance has traditionally been low. Also, inactivated vaccine should be given to family members of high-risk infants. Little is known about the safety and efficacy of using antiviral prophylaxis for staff members and parents in epidemics in the NICU, although they have been used.[49]

Most influenza infections in neonates are asymptomatic. Infection is less common in the first 6 months of life and usually less symptomatic, probably reflecting the transplacental transference of maternal antibody during pregnancy, which may protect the infant for the first 6 months, and antibody transferred via breast milk. Infants may present with high fever and an upper respiratory tract infection, however, and infection may be indistinguishable from bacterial sepsis. Infants younger than 6 months have also been reported to have the highest mortality. In the 2003-2004 influenza season, the mortality of infants younger than 6 months was 0.88 per 100,000 children. One third of the infants died at home, and one fourth had coinfections with bacteria. Only one third had conditions recognized as putting the infant at high risk, such as pulmonary or cardiovascular disease or immunosuppression. Chronic neurologic and neuromuscular conditions, not previously recognized as at-risk conditions, were present in one third of the children.[9]

Bronchiolitis, pneumonia or croup, fever, rhinorrhea, apnea, irritability, and feeding difficulties all may be primary symptoms. In a prospective study of the first year of life, one third of the infants were infected, but only 40% of the infants were infected in the first 6 months of life, and most lower respiratory tract disease and otitis media occurred in the latter 6 months, when the transferred maternal antibody would be expected to have waned.[44] There was also a very significant increase in risk of infection with increasing numbers of siblings, ranging from a 20% infection rate with no siblings to a 59% rate with three or more siblings. Lower respiratory tract disease was, however, far less common than with RSV or PIV. One third of infants presenting to the emergency department during influenza epidemics had influenza infection, although they frequently had no respiratory symptoms. In contrast, one third of the infants presenting with a community-acquired pneumonia were also infected with influenza.[77,117]

Several influenza A and a few influenza B epidemics have been reported in NICUs. Low rates of immunization among staff members played a significant role in these epidemics. Prematurity and pulmonary disease, particularly bronchopulmonary dysplasia, seem to be risk factors.

There is no antiviral treatment licensed for use in infants younger than 1 year of age. Amantadine has been used in NICU outbreaks, but did not seem to decrease the length of illness, and in one instance resistance was quickly noted.[29,100] The safety of any of the antiviral drugs has not been determined in infants. Likewise, inactivated influenza vaccine is not licensed for infants 6 months or younger because it has not been shown to be immunogenic, even though infants, especially infants with bronchopulmonary dysplasia, may be at greater risk than older children. Instead, the risk of exposure to these infants should be minimized by immunizing health care workers and family members and other close contacts. Vaccination of preterm infants after 6 months of age, even in the presence of prolonged hypogammaglobulinemia, does result in a good antibody response.[127]

NOVEL H1N1 INFLUENZA A

Novel H1N1 influenza A was first recognized in Mexico and the United States in March and April 2009. It was initially called "swine flu" because it seemed to be genetically related to the influenza viruses that occurred in pigs in North America. It has now been shown, however, that novel H1N1 influenza A is a reassortment virus of two genes that circulate in swine in Europe and Asia and bird (avian) genes and human genes. In April 2009, the United States declared a public health emergency and began working on pandemic alert level; this was based on the spread of the virus rather than its severity. The virus continued to spread, and outbreaks occurred in the United States throughout the summer in 2009. The United States has the highest number of cases in the world, although most patients recovered and did not experience severe illness. In the Southern Hemisphere, when it entered its influenza season in 2009, cases of novel H1N1 virus spread in addition to the regular seasonal influenza virus.

At the present time, limited data are available regarding the spread, infection, prevention, and treatment of novel H1N1 influenza. The following data and recommendations are current as of the writing of this chapter, but will undoubtedly be changing as more data are accrued. These recommendations were obtained from the website of the CDC (www.cdc.gov/h1n1flu); this site should be consulted regularly for changes in recommendations.

The novel H1N1 virus seems to spread via the same mechanisms as the regular influenza virus, by large particle respiratory droplet transmission, which occurs when a person coughs or sneezes. The particles travel only a short distance (<6 feet) because of their size. Influenza virus may also survive and remain infectious on environmental surfaces for 2 to 8 hours. Small droplet or airborne transmission is also possible. It is not spread by eating food, including pork or pork products. The virus can be destroyed by heat (75°C to 100°C) or by numerous chemical germicides or household disinfectants, including chlorine, detergents, hydrogen peroxide, and alcohols. Most importantly, hand washing with soap and water and with alcohol-based hand cleaners is very effective. Individuals should cover their nose and mouth with a tissue when coughing or sneezing; wash their hands frequently; and avoid touching their eyes, nose, and mouth. Individuals with a flulike illness should remain at home.

Infection may be mild or severe. The symptoms are the same as for seasonal influenza: fever, cough, sore throat, aches, chills and fatigue, headache, running or stuffy nose, and vomiting and diarrhea. Young children may not develop fever, but are more likely to have diarrhea. Complications may be mild (otitis, febrile seizures) or severe (bacterial coinfeciton, pneumonia or worsened baseline conditions) and may progress very rapidly. Pneumonia was seen in nearly half of children who were less than five years of age.[61a] Hospitalization was required in 35% of one month old infants and 21% of two month old infants.[85a]

- Children younger than 5 years (highest risk is for children <2 years old)
- Pregnant women
- Adults 65 years old and older
- People with chronic conditions
    - Chronic pulmonary (asthma), cardiovascular, renal, hepatic, hematologic (sickle cell disease), neurologic, neuromuscular, or metabolic disorders (diabetes)
    - Immunosuppression, either by medication or HIV infection or cancer or chronic steroids
    - Individuals younger than 19 years old on long-term aspirin therapy

There are four influenza antiviral drugs available for use. The novel H1N1 influenza virus is sensitive to date to the neuraminidase inhibitors, zanamivir and oseltamivir, but resistant to the adamantine medications, amantadine and rimantadine. Treatment should be started as soon as possible after onset of symptoms in all hospitalized patients with suspected, probable, or confirmed novel H1N1 infection, and in patients who are in a high-risk group for seasonal influenza complications. Treatment benefit seems to be greatest when treatment is started within 48 hours of symptom onset, but data from patients with seasonal influenza indicate that there may be some decrease in mortality and hospital stay even when started after 48 hours. Treatment should continue for 5 days.

There are limited safety data for oseltamivir in children younger than 1 year of age, which indicate that serious adverse effects are probably rare, and this group has had significant morbidity and mortality from seasonal influenza. Infants less than three months should not receive chemoprophylaxis unless the situation is felt to be critical. Oseltamivir may be considered for treatment (3 mg/kg/dose twice daily for 5 days). Premature infants have immature renal function and may have slower clearance of oseltamivir. There are insufficient data to recommend a dose and drug concentrations that have been measured are highly variable.

Pregnant women infected with H1N1 influenza virus in 2009 had higher rates of hospitalization and represented about 6% of all the deaths in the United States. They should be vaccinated during prenatal visits and may receive both seasonal flu vaccine and H1N1 flu vaccine at the same time in different sites (one in each arm). Vaccination of the pregnant woman may offer some protection to her newborn infant, which is particularly important, as the vaccine is not licensed for infants less than six months of age. Certainly, all caregivers of infants less than six months should also be vaccinated in an effort to prevent them from bringing influenza to the infant. Pregnant women should receive the monovalent injectable, inactivated vaccine with or without themerosol preservative. Breast feeding is likewise compatible with vaccination and may offer some antibody protection to the infant. Both the nasal spray or injectable vaccine may be given to the breast feeding mother.

The virus has not been shown to cross the placenta to date, but the newborn may be exposed to contaminated secretions at birth. Thus, the newborn should be considered exposed rather than infected, and should be carefully observed. The baby may be separated from the mother in an incubator in the same room, or in a separate room until the mother has been treated with antivirals for at least 48 hours and has been free of fever while off antipyretics for at least 24 hours, and can control her cough and respiratory secretions. Breast feeding should be fully supported and the breast milk should be used to feed the newborn. When able to see her infant, the mother should wear a face mask, wash her hands with soap and water, and follow respiratory hygiene and cough etiquette guidelines for at least seven days after symptom onset or 24 hours after resolution of symptoms, whichever is longer.

In past pandemics, secondary bacterial infections, particularly caused by *Streptococcus pneumoniae* (pneumococcus), have also been the cause of increased morbidity and mortality. Continued pneumococcal vaccination is important.

RUBELLA VIRUS

Rubella virus is an RNA virus in the Togaviridae family. It is surrounded by a lipid-containing envelope, which is responsible for its infectivity. Only one immunologic strain has been identified; the epidemics that have occurred seem to be secondary to changes in the susceptibility of the population, rather than changes in the virulence of a strain.

Rubella produces a very mild but extremely contagious disease, sometimes referred to as German measles. The incubation period is 14 to 23 days. It primarily manifests in adults with a maculopapular rash that can last 3 days and spreads from the face to the trunk and extremities, and with postauricular, suboccipital, and posterior cervical lymph node enlargement. There may be conjunctivitis, headache, sore throat, and cough. Although arthralgias may occur, recovery is nearly always rapid and complete. Fever is slight. Thrombocytopenia and encephalitis are rare. Half of all infections may be asymptomatic.

Epidemiology and Transmission

Rubella virus exclusively infects humans and is spread via respiratory droplet contact. Infections are worldwide in distribution, but tend to peak in late winter and early spring. Presumably, the viral reservoir is maintained by mild or asymptomatic infections that occur constantly throughout the year and by prolonged viral shedding (possibly ≥1 year) from congenitally infected infants. Most individuals shed virus from 7 days before the onset of the rash until 14 days afterward. In the prevaccine era (before 1969), epidemics occurred every 6 to 9 years. The last major epidemic in the United States was in 1965. The goal of routine rubella vaccination in the United States, begun in 1969, was to eliminate congenital rubella syndrome. From 2001-2006, there were only four cases of congenital rubella syndrome in the United States. Three of the mothers were born outside of the United States.[93] In 2004, the CDC declared that rubella was no longer endemic in the United States. Rubella continues to occur among immigrants, however, and it is important that pediatricians continue to administer the vaccine. The current goal is global elimination.

Most cases of congenital rubella syndrome occur after a primary maternal infection that causes viremia and intrauterine transmission. A few cases have occurred after maternal reinfection with rubella, but these are very rare. Accidental vaccination with RA27/3 vaccine in pregnancy may result in fetal infection (2%), but congenital defects or congenital rubella syndromes have not been seen.

After a primary maternal infection in the first trimester, there may be fetal loss, stillbirth, placental infection, or congenital rubella syndrome, or the fetus may remain totally uninfected. Not all infected fetuses develop congenital rubella syndrome. The virus may cause persistent placental infection with or without persistent fetal infection. The placenta is a relatively effective barrier to fetal infection from 12 to 28 weeks' gestation, but is not so effective in the first and third trimesters, particularly in the last month of pregnancy.

Gestational age at the time of maternal infection is the most important determinant of fetal infection and of the development of congenital defects, although fetal infection may occur at any point in gestation. Among 273 infants delivered after maternal rubella infection, Miller and colleagues[95] reported that fetal infection occurred in 90% of infants after maternal infection before 11 weeks' gestation, in 67% of infants at 13 to 14 weeks' gestation, and in 25% of infants at 23 to 26 weeks' gestation. Infection increased to 53% of infants after maternal infection in the third trimester, however, and reached 100% in the last month of pregnancy.

In addition, the risk of fetal damage with fetal infection decreases with increasing gestational age. Peckham[113] followed 218 congenitally infected infants for 2 years and found that fetal damage occurred in 52% of infants infected before 8 weeks' gestation, in 36% of infants infected at 9 to 12 weeks' gestation, and in 10% of infants infected at 13 to 20 weeks' gestation. No fetal damage was shown after infection beyond 20 weeks' gestation. Rubella results in chronic infection of the fetal tissues, however, causing an inhibition of fetal cell multiplication. Many infants who show no apparent involvement at birth develop consequences years later. In concordance with the chronicity of the disease, Peckham[113] later noted that at 6 to 8 years of age, these same infants had an 82% risk of sequelae after infection in the first trimester. The risk of fetal damage reported by Miller and colleagues[95] was even higher, with sequelae shown in 90% of infants infected before 11 weeks' gestation, 33% infected from 11 to 12 weeks' gestation, 11% infected at 13 to 14 weeks' gestation, and 24% infected at 15 to 16 weeks' gestation.

Congenital Rubella Syndrome

Congenital rubella is not a static disease. Nearly three fourths of infected infants show no apparent involvement at birth, but develop consequences years later. More than half of infants with expanded congenital rubella syndrome have intrauterine growth restriction (birthweight is often <1500 g) and continue to fail to thrive postnatally. These infants often have myriad transient symptoms, including thrombocytopenia, petechiae and purpura, hemolytic anemia, hepatitis, jaundice, and hepatosplenomegaly. Nearly half of infants show "blueberry muffin" spots on the head, neck, and trunk, which represent dermal extramedullary hematopoiesis. Infants may also show myocarditis, cloudy cornea, long bone radiolucencies, interstitial pneumonia, and meningoencephalitis, manifested by an elevated CSF protein level and pleocytosis. Although most of these symptoms are transient, they may also indicate severity of infection. Fulminant hepatitis or pneumonia, myocarditis with congestive heart failure, meningoencephalitis, thrombocytopenia, and bony lesions all are associated with a higher mortality.

Congenital rubella is best known for causing deafness and defects of the eye, CNS, and heart. Three fourths of infants develop sensorineural deafness, usually bilateral. Deafness may be the only sequela of congenital infection and may occur with maternal infection up to 20 weeks' gestation.

Congenital heart disease occurs only when the fetus is infected during the first 8 weeks of gestation, the period during which organogenesis occurs, but is quite common with infection during that period. Patent ductus arteriosus, the most common lesion, may occur alone or in conjunction with pulmonary artery or valvular stenosis, or there may be stenoses of other vessels.

Microcephaly and neuropsychiatric problems are also common. Studies of long-term outcome show that 26% of children with congenital rubella syndrome were severely mentally retarded, 12% had neurologic problems, 18% had behavioral abnormalities, and 6% had autism. Most rubella survivors without mental retardation had learning disorders, behavioral problems, difficulties with balance, and muscle weakness.

Ophthalmologic abnormalities may include cataracts in one third of children, often bilateral and occasionally accompanied by glaucoma. Other children may have microphthalmos or characteristic salt-and-pepper chorioretinitis. Rubella RNA can be detected and quantified in the lens of affected infants.

Attention has focused more recently on the effects of HLA haplotypes, immune complexes, and autoantibodies in predisposing congenital rubella survivors to autoimmune conditions. In a 60-year follow-up of congenital rubella survivors, Forrest and colleagues[38] showed that 20% had died (mostly of cardiovascular disease and malignancy); 68% had mild aortic valve stenosis, 22% had diabetes mellitus, 19% had thyroid disease, 73% had early menopause, and 13% had osteoporosis. HLA-A1 and HLA-B8 antigens were increased in frequency.

Diagnosis

Diagnosis of maternal rubella on the basis of clinical findings is unreliable, and serologic testing must be used. If the maternal immune status is unknown at the time of rash illness, acute-phase titers should be obtained within 7 days of the illness; seropositivity usually indicates prior immunity with very little risk of current infection. Women with very low titers may be reinfected, which can result in a small risk of fetal infection. Latex agglutination, enzyme immunoassay tests, and immunofluorescence are now more commonly used than passive hemagglutination techniques.

Rubella-specific IgM may be determined 7 to 14 days after the illness. A high or moderate IgM titer is very helpful, but false-positive results may occur, and low IgM titers may be found in patients with subclinical reinfection. Testing IgG avidity can be very helpful in differentiating acute infection from reinfection, postvaccination, and false-positive IgM values.

Traditionally, an increase in serum antibody titers obtained initially in the acute phase, preferably within 7 days of illness, and repeated in the convalescent phase, 10 to 14 days later, is used to diagnose acute infection. The titers need to be run simultaneously in the same laboratory. If antibody is still not present 4 weeks after exposure, another serum sample should be tested at 6 weeks for certainty. Acute-phase titers may be obtained, with less accuracy, 28 days after illness, but are not interpretable thereafter.

The antenatal diagnosis of fetal rubella infection has been made with rubella cultures or detection of rubella-specific IgM or rubella-specific antigen or RNA by reverse transcriptase PCR from amniotic fluid or percutaneous umbilical blood sampling. Chorionic villus sampling has also been used, but less is known of its reliability.

Any infant born to a mother suspected of having had a rubella infection in pregnancy or born with clinical signs and symptoms consistent with congenital rubella syndrome should have a complete evaluation and diagnostic workup. Isolation of rubella virus from a newborn provides an absolute diagnosis. The virus is most often isolated from the nasopharynx, but has been grown in the blood, CSF, and urine, or even from the lens of the eye or CSF years later. The diagnosis may also be made by detecting rubella-specific IgM in cord or infant blood or by detecting stable or increasing concentrations of rubella-specific IgG in the infant's serum over several months, although hypogammaglobulinemic infants may fail to produce antibody. More recently, oral fluid testing for rubella-specific IgM or reverse transcriptase PCR for rubella antigen has been very helpful.

Prevention and Therapy

All children with postnatally acquired rubella should be isolated for 7 days after the rash appears. In contrast, children with congenitally acquired rubella should be considered contagious for at least 1 year, unless repeated urine and blood cultures are negative. In addition, the families of these infants should be counseled regarding the risks to pregnant women.

Susceptible pregnant women exposed to rash illnesses should have a laboratory workup performed for diagnosis, as should the individual who is the origin of the illness. Immune globulin is not recommended for prophylaxis in an exposed pregnant woman unless abortion is absolutely not a consideration because congenital rubella has occurred despite the lack of symptoms in women given immune globulin. Also, vaccination after exposure does not prevent infection from the current exposure, but might prevent exposure and infection in the future.

The goal in the United States is to eliminate rubella with vaccination. The RA 27/3 rubella virus vaccine is exclusively used in the United States and is highly effective. Infants should be vaccinated at 12 to 15 months of age and again at school entry. Preterm infants seem to lose maternal antibody to rubella at a much earlier age than term infants because the antibody is transferred primarily during the third trimester. The antibody response to vaccination is similar, however, to that of term infants. Postpartum and postpubertal women should be vaccinated unless contraindication exists. Breast feeding is not a contraindication. Women should not be vaccinated during pregnancy because 3% of fetuses may be infected, but birth defects have not been reported after vaccination of pregnant women, even if the fetus is infected. It is acceptable to vaccinate children of pregnant women because there is no evidence of transmission of virus after vaccination. Some parents continue to believe that vaccination with MMR may cause autism, despite numerous data and studies failing to show any association. The Immunization Safety Review Committee of the Institute of Medicine rejects any causal association.

RHINOVIRUS

Rhinoviruses are the most prevalent of human pathogens and are well known to cause the "common cold." They are small, nonenveloped RNA viruses classified as picornaviruses. There are three large groups of human pathogens among the Picornaviridae family: the enteroviruses (enteroviruses, polioviruses, coxsackieviruses, and echoviruses), the hepatoviruses (hepatovirus A), and the rhinoviruses. There are more than 100 rhinovirus serotypes, and even more serotypes are being described with improved methodology. Immunity to one serotype offers little immunity to another and is only of variable and brief duration to that serotype. The rhinoviruses are usually spread from person to person via contaminated hands and self-inoculation of the nasopharynx, but may also be spread by aerosol droplets. Infection may occur year-round, but may be epidemic in fall and spring, in temperate climates; the incubation period lasts 2 to 7 days. Shedding has been documented for up to 3 weeks. Cell culture of the nasopharynx has a low sensitivity of diagnosis. PCR shows the prevalence and importance of this virus, particularly in infancy and early childhood.

A series of reports on 285 infants at high risk of developing asthma, who were followed to 6 years of age, emphasized the importance that rhinovirus infections play in the first year of life.[60] Human rhinovirus was the most common etiology of upper respiratory tract infection (48%) and occurred early and repetitively in these high-risk infants. Coinfection with other viruses generally resulted in more severe upper respiratory tract infections.[62] Higher rates of infection were found in children enrolled in daycare or with siblings in the home. A wheezing illness caused by rhinovirus at any point in the first 3 years of life in these high-risk infants resulted in a 10-fold increase in risk of asthma at 6 years of age—much more of a risk than found with RSV wheezing illness in early childhood (Fig. 39-16).[60]

Because rhinovirus is now known to cause lower respiratory tract disease, it is likely that it enhances susceptibility to asthma in predisposed children. It is known that low interferon-γ responses in infancy increase the risk of viral illness and of wheezing during infancy.[60] Many other reports have now verified rhinovirus as the most important cause of upper and lower respiratory infections; it is responsible for five hospitalizations per 1000 children younger than 5 years of age each year, which is far more significant than found for RSV.[75,96]

There is no effective treatment, and the only prophylaxis is use of infection control measures, such as contact precautions and hand washing. Rhinoviruses have also now been shown to be the etiology of sporadic, individual infections, or outbreaks, in the NICU. Infants may present with apnea, feeding difficulties, cough or rhinitis, and fever. Signs and symptoms may be indistinguishable from RSV. Young infants seem to be particularly susceptible to rhinovirus. Infants with bronchopulmonary dysplasia may develop a lower respiratory tract disease that is as likely to require intensive care admission as RSV. Preterm infants with bronchopulmonary dysplasia who were readmitted with rhinovirus had significant worsening of their pulmonary status, necessitating prolonged increases in care.

SEVERE ACUTE RESPIRATORY SYNDROME

In 2003, an epidemic of severe acute respiratory syndrome (SARS) occurred in China, Hong Kong, Vietnam, and Canada, and was eventually reported in 16 countries, including the United States. A novel coronavirus, unrelated to the other known human and animal coronaviruses, has been shown to be the cause of the outbreak. The horseshoe bats of southern China were found to be the natural reservoir of this enveloped RNA virus, and it can spread to a wide variety of other animals. It is feared that the virus will again spread from animal to human and cause future outbreaks. Exposure and travel histories need to be obtained in all severe respiratory outbreaks.[10]

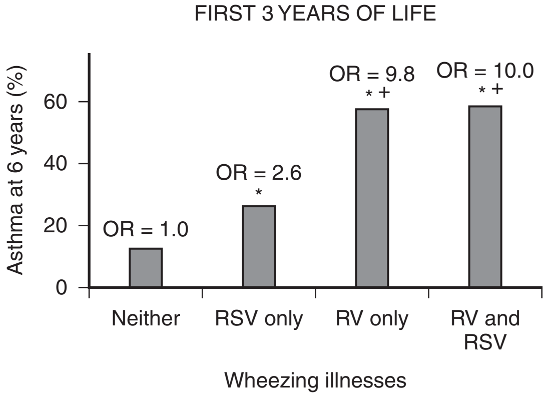

Figure 39–16. Risk of asthma at age 6 years in children who wheezed during the first 3 years of life with rhinovirus (RV), respiratory syncytial virus (RSV), or both (*P, .05 versus neither; +P, .05 versus RSV only). OR, odds ratio. *(From Jackson DJ et al: Wheezing rhinovirus illnesses in early life predict asthma development in high-risk children,* Am J Resp Crit Care Med *178:667, 2008.)*

Virtually all cases of SARS in children have occurred via contact with infected adults, either in the home or in a health care setting. Coinfection may occur with other viral pathogens, but it is unknown what role coinfection plays. Less than 10% of infections have occurred in children. The virus causes a mild, nonspecific respiratory illness in younger children, in contrast to the very serious, life-threatening infection in adults and teenagers older than 12 years. Most children present with fever, but may have cough, coryza, myalgia, malaise, chills, or diarrhea.[83]

In young children, the physical examination is normal, and the course is shorter and milder. As a group, young children apparently do not develop significant respiratory distress or require oxygen, and they make a complete recovery. Chest auscultation is unimpressive. The chest radiograph shows mild focal alveolar infiltrates. (In some cases, high-resolution CT showed airspace disease even though the chest film was negative.) Less than 1% of children require mechanical ventilation.[83] Similar to adults, children have multiple laboratory findings, including lymphopenia from destruction of the CD4+ and CD8+ lymphocytes, thrombocytopenia, and mild disseminated intravascular coagulation. Lactic dehydrogenase is also elevated in most cases. No deaths have occurred in young children, and they are asymptomatic within 6 months. Most reports of infections in children begin with infants a few months old. One premature infant presented at 56 days of life, at a corrected age of 38 weeks. His illness was comparable to that of adults, requiring oxygen, continuous positive airway pressure, and NICU admission, although he made a complete recovery.[135]

No infants born to mothers infected with SARS-COV (coronavirus) have shown any evidence of transplacental or congenital infection. Pregnant women may be more severely affected, with mortality of 25%. Only one infant survived of seven pregnancies in women infected in the first trimester in Hong Kong, but two less severely affected women in the United States had infants with normal outcomes. Infants born to mothers infected in the second or third trimester seem to survive, whether born via cesarean section prematurely because of the mother's deteriorating condition or vaginally at term to a convalescent mother. None of the infants had evidence of infection. Infants born soon after the mother is infected tend to be appropriately grown, whereas infants born later have intrauterine growth restriction and oligohydramnios[83]; this could be secondary to the use of ribavirin or steroids for the mother's illness or because of the mother's illness itself. Infants born prematurely had a high incidence of necrotizing enterocolitis and jejunal perforation. Extensive fetal thrombotic vasculopathy with zones of avascular villi was noted in the placentae of two infants who survived a maternal SARS infection.[102]

Diagnosis of disease in children may be based on the World Health Organization definition of probable SARS (radiographic evidence and epidemiologic linkage) or the CDC definition of suspect SARS (radiographic evidence is unnecessary). Children seem more likely to have negative reverse transcriptase PCR tests and viral cultures, possibly because of a lower viral titer in the upper airway.

Infected individuals should be quarantined, preferably in a negative pressure room, and there should be strict adherence to infection control principles to prevent spread via aerosol, droplet, or fomites. There have been no documented cases of transmission of infection from children to adults, but there have been cases of not yet symptomatic parents infecting health care workers. This situation may represent lower viral titers in the children. Closed circuit scavenger systems should be built into ventilator systems, and continuous positive airway pressure, oxygen flow, or nebulizers should be used only within an isolette.

At this time, ribavirin does not seem to be useful in the treatment of most routine cases of SARS. The use of aerosols, such as albuterol, and continuous positive airway pressure may potentiate spread to other individuals. High-dose steroids, ribavirin, and oxygen and ventilation, as needed, have been the mainstays of treatment offered to date.

WEST NILE VIRUS

West Nile virus (WNV) is a single-stranded RNA flavivirus, transmitted to humans by the bites of infected mosquitoes. This arbovirus (arthropod-borne) survives in nature in a cycle that goes from mosquito to bird to mosquito, and primarily involves the *Culex* species of mosquitoes. It is a neuropathogen of humans, equines, and birds (especially crows). Infection has also been associated with transfusions or organ transplants from infected donors. Indigenous to Africa, Asia, Europe, and Australia, WNV was first reported in the Western Hemisphere in 1999 in an epizootic in New York City. Since then, it has rapidly spread throughout eastern and midwestern parts of the United States. Human infection may be asymptomatic (80%) or result in simple West Nile fever (20%) or invasive meningoencephalitis (<1%). Diagnosis is made by testing serum and CSF for WNV-specific IgG and IgM. The specificity, sensitivity, and predictive value of IgM and IgG in breast milk and neonatal or cord blood are unknown. There is no specific treatment for infection or vaccine to prevent infection. Preventive measures are the only defense and involve mosquito control and the education of the public to wear protective clothing, to use insect repellant on skin and clothing when outdoors, and to avoid the outdoors during peak mosquito hours (dusk to dawn).

There have been few reports of WNV infections in children younger than 1 year of age. Breast feeding was implicated in a report that came from Michigan, in 2002, when an infant was found to have WNV-specific serum IgM after breast feeding for 17 days. The mother developed WNV meningoencephalitis 9 days after receiving an infected transfusion, given after the birth of the infant. WNV genetic material was detected transiently in the breast milk. The infant remained well. No other cases of breast milk transmission have been proven, and transmission via human breast milk seems to be rare.[54] The benefits of breast feeding are well established, so there are no changes in the recommendations for breast feeding.

Intrauterine infection was probably documented in 2002 in the fetus of a mother who developed paraplegia secondary to WNV during the second trimester of her pregnancy.[4] The infant appeared well at term and had a normal physical examination, including head circumference. Ophthalmologic examination revealed marked chorioretinal scarring, however, and MRI of the brain showed generalized lissencephaly and marked white matter loss. In a survey in Colorado during an epidemic, 549 cord blood samples were screened for WNV-specific IgG and IgM. Of the cord samples, 4% were positive for IgG, indicating maternal infection, but none were positive for IgM, and all infants had normal growth and outcome.[109] Likewise, the CDC followed the outcome of 77 pregnancies in which the mothers were infected with WNV. There were four miscarriages and two elective abortions. Of the 72 live-born infants, none had conclusive evidence of congenital infection, although three infants developed infections that might have been congenitally acquired. Seven infants had major malformations, but only 3 of these could have been related to infection, and none of these infants had evidence of infection.[107]

The CDC has developed guidelines for the evaluation of infants born to mothers infected with WNV during pregnancy and a registry for pregnancy outcome.[147] Screening for WNV in asymptomatic, pregnant women is not recommended because there is no therapeutic intervention, and the outcome is currently unknown. A detailed ultrasound examination of the fetus should be obtained no earlier than 2 to 4 weeks after the onset of symptoms in an infected pregnant woman. Amniotic fluid, chorionic villi, and fetal serum may be tested for infection; in the event of a miscarriage or abortion, all products of conception should also be tested. Infants born to women known to be infected during the pregnancy should have a thorough physical examination, including measurements of head circumference, length and weight; a neurologic examination; and evaluation for dysmorphic features, any dermatologic lesions, or hepatosplenomegaly. The infant's serum should be tested for IgG and IgM specific for WNV, and the infant should have evoked otoacoustic emissions testing or auditory brainstem response testing. The placenta should also be examined by a pathologist.

An infant suspected to have WNV infection should undergo an extensive workup, including a CT scan of the head and an ophthalmologic examination. The infant should have a complete blood count and liver function tests. Examination of the CSF should be considered and should include an IgM for WNV. The infant should be examined by a dysmorphologist, and developmental milestones and growth measurements should be followed for the first year of life. At 6 months of life, the infant should have an additional hearing screen and determination of WNV IgG and IgM.

ADENOVIRUS

Adenoviruses are double-stranded, nonenveloped DNA viruses. The six groups (A through F) have multiple distinct serotypes, and the different serotypes cause different kinds of illness. The virus is most commonly found in the upper respiratory tract, and infection usually spreads via respiratory tract secretions. The virus is viable in the secretions for long periods, so fomites contaminated with secretions may transmit infection, in addition to aerosolized droplets and person-to-person contact. Viral shedding may occur intermittently for months after infection. Individuals may be reinfected and have asymptomatic infection. Health care workers and equipment, particularly ophthalmologic, have been implicated as sources of infection, so control requires careful hand washing and contact and droplet precautions. Infected health care workers should not participate in direct patient care for 2 weeks after onset, and should use gloves in addition to strict hand washing. Ophthalmologic medications should be single-dose in nature, and equipment needs careful sterilization. Daycare of young infants and children is another frequent source of infection, for which there are few effective control measures other than careful hygiene because the virus is also shed in the stool.

Adenovirus is most often associated with the "common cold," pharyngitis, otitis media, or pharyngoconjunctival fever. Respiratory infections are most common in late winter to early summer. Enteric strains cause gastroenteritis, more often in young infants and children, and occur year-round. Epidemic keratoconjunctivitis can be spread from contaminated water in inadequately chlorinated swimming pools in summer or from ophthalmologic equipment.

Although older children and healthy adults usually have self-limited, acute infections, infants and neonates, especially premature infants, may develop disseminated disease with a high mortality. The serotypes most commonly found (85%) in children are not as commonly found in infants younger than 6 months, suggesting that transplacental maternal antibody may be protective.[115]

Young infants, similar to immunocompromised individuals, may develop disseminated infections, pneumonia, bronchiolitis, or meningoencephalitis. In this instance, infection may be confused with invasive bacterial disease. The degree of inflammation is indicated by the considerable elevation of C-reactive protein. These infants are usually infected with subgroup B viruses (serotypes 3, 7, 21, and 35) and, less commonly, with subgroup D viruses (serotypes 2 and 32). Mortality, which may be 80%, is at its highest in the first 2 weeks of life. These infants may develop pancytopenia, disseminated intravascular coagulation, pleural effusion, wheezing, and hepatitis. Pneumonia may be fatal, and, if survived, may result in significant lung damage, necessitating increased respiratory support for months.

Several reports have documented outbreaks of epidemic keratoconjunctivitis secondary to serotype 8 in NICUs.[23,116] Affected infants have lid edema, erythema, fever, and, less commonly, conjunctivitis. They also develop acute and chronic respiratory manifestations.

Adenovirus type 30 was identified more recently as the source of an outbreak in the NICU affecting 21 infants.[34,115] Type 30 is a D group adenovirus not previously identified in NICU outbreaks, although D group adenoviruses have been known to cause gastrointestinal infections and keratoconjunctivitis. Eight infants developed pneumonia (of whom seven died), and eight infants developed conjunctivitis. Five asymptomatic infants were detected only by surveillance cultures. Several items of importance were noted in this report. The ophthalmologists, who had upper respiratory infections but continued to work, and who did not completely follow the American Academy of Ophthalmology infection control best practices, seemed to have a major role in this outbreak. Infection control measures were successful, but were discontinued too soon, before all infants had stopped shedding virus, and the outbreak began again. Finally, steroid use in the infants with pneumonia was highly associated with mortality.[34,115]

Reports of intrauterine or postnatal myocarditis owing to adenovirus have been increasing. Finally, evidence is accumulating for the rare case of congenital infection.[25] These infants die of disseminated disease and are small for gestational age. They may have necrotizing pneumonia, hepatitis, meningitis, myocarditis, and nephritis.

Diagnosis of adenoviral infection can be made by tissue culture, shell vial technique, or antigen detection via immunofluorescence in the pharynx, eye, body fluids, or stool. PCR is the most sensitive and specific test, although the most expensive. There is no effective, specific antiviral therapy that is not too toxic. Treatment is supportive.

HUMAN PAPILLOMAVIRUS

Human papillomavirus (HPV) is a double-stranded, nonenveloped DNA virus. The organism cannot be propagated in cell culture, and its presence is detected by the identification of viral DNA from tissue samples. Infection by HPV usually is asymptomatic. A few infected adults develop mucocutaneous lesions, most commonly cutaneous and genital warts and neoplasms of epithelial surfaces, especially the uterine cervix. HPV can be typed according to DNA sequence, and more than 100 genotypes have been identified. The different types can be distinguished by their propensity to cause low-grade warts (particularly types 6 and 11) versus high-grade, carcinomatous lesions (particularly types 16 and 18). Genital HPV infection in adults is usually transmitted by sexual contact. Nonsexual modes of acquisition, such as autoinoculation and heteroinoculation, are suspected, however.

Genital HPV is increasingly easier to detect in infected women during pregnancy, presumably reflecting increased viral activity. Virus can be transmitted to the newborn, but the timing, frequency, and consequences of vertical transmission of HPV are matters of debate. Although some studies suggest vertical transmission occurs in more than half of pregnancies involving women with known HPV-related genital lesions, more recent investigations indicate a far lower rate.[137] HPV isolated from the pharynx or genital tract of the infant soon after birth frequently is discordant from HPV found in the mother, suggesting at least some neonatal acquisition by horizontal routes. HPV detected soon after delivery usually causes no clinically detectable disease, and evidence of infection disappears within a few months[88]; seroconversion to the initially detected virus is unusual.

The childhood disease most strongly associated with vertically transmitted HPV is juvenile-onset recurrent respiratory papillomatosis (JORRP). This illness, which usually becomes clinically apparent by 2 to 3 years of age, is characterized by the development of multiple benign laryngeal papillomas. These lesions require repeated surgical excision to avoid airway obstruction. Occasionally, papillomas spread to the lower respiratory tract. JORRP is most strongly associated with HPV types 6 and 11, and often there is a history of condylomatous lesions in the mother caused by HPV of the same type.[133] The prevalence of JORRP is approximately 2 per 100,000 persons younger than 18 years, far lower than the prevalence of genital warts in pregnant women, suggesting that most infants exposed to HPV types 6 and 11 during birth remain unaffected.

Some, but not all, studies suggest a lower risk of JORRP if the infant is delivered by cesarean section, but operative delivery is not always protective, and it is not routinely recommended in a pregnant woman with genital warts. It is suspected that vertically transmitted HPV also can result in the development of anogenital warts in the child within the first several years of his or her life, presenting a dilemma to the child's caregivers because identical lesions can be associated with sexual abuse.

In the mid-2000s, a tetravalent recombinant HPV vaccine was introduced containing the major capsid proteins of HPV types 6, 11, 16, and 18. In the United States, this vaccine is recommended for females age 9 through 26 years, administered, it is hoped, before the natural acquisition of HPV through sexual activity. Because laryngeal and anogenital disease in newborns are caused primarily by HPV types 6 and 11, the broad application of this vaccine has the potential to reduce significantly mother-to-child transmission of HPV infection, although it is presumed to require many years of immunization before this potential is fully realized.

LYMPHOCYTIC CHORIOMENINGITIS VIRUS

Lymphocytic choriomeningitis virus (LCMV) is a member of the Arenaviridae family. Rodents, particularly the house mouse and pet hamsters, serve as the principal reservoirs for LCMV. Humans acquire the virus by inhaling aerosolized droppings or by coming into direct contact with an infected animal. Human infection is probably more common than appreciated. Serosurveys among healthy adults from various parts of the world have detected LCMV antibodies in 3% to 5%. Most cases in adults are mildly symptomatic or manifest with nonspecific, self-limited flulike symptoms. Uncommonly, these progress to aseptic meningitis or encephalitis.

LCMV crosses the placenta to cause intrauterine infection. Few cases of congenital disease have been published, but these reports describe a striking and common phenotype. Most manifestations in the newborn are confined to the CNS and the eyes.[11] Infants typically are born with either microcephaly or macrocephaly, the latter the consequence of aqueductal stenosis and hydrocephalus. Neuroimaging studies frequently reveal periventricular calcifications and patchy abnormalities of white matter. Most infants are left with severe visual and neurologic impairment. More than 90% of reported cases have chorioretinitis with scarring and visual impairment. Hearing usually is preserved. Manifestations outside the CNS (liver and heart dysfunction and thrombocytopenia) have occasionally been described, but are uncommon.

In many cases, the mother recalls an influenza-like illness early in pregnancy, but only a few remember exposure to rodents. The diagnosis is supported by measuring anti-LCMV IgM and IgG. Antibodies to LCMV are sufficiently uncommon in the general population that their presence in an infant with typical CNS findings is sufficient to establish the diagnosis, especially in the absence of alternative possibilities, such as toxoplasmosis and CMV.

CHAPTER 40

The Central Nervous System

PART 1

Normal and Abnormal Brain Development

Pierre Gressens and Petra S. Hüppi

MECHANISMS OF BRAIN DEVELOPMENT

Normal development of the human central nervous system (CNS) encompasses several steps, including neuroectoderm induction, neurulation, cell proliferation and migration, programmed cell death, neurogenesis and elimination of excess neurons, synaptogenesis, stabilization and elimination of synapses, gliogenesis, and myelination (Table 40-1).

These different steps of brain development and maturation are controlled by the interaction between genes and environment. Numerous genes involved in brain development have been identified: genes controlling neurulation, neuronal proliferation, neuronal size and shape, programmed cell death, neuronal-glial interactions, and synaptic stabilization.[105] However, it seems unlikely that the 30,000 genes in humans can totally control the organization of 100 billion neurons and trillions of synapses. A normal pattern of expression of these genes requires an adequate environment. Interactions with the intrauterine milieu (factors coming from the mother, placenta, or amniotic fluid) and with the postnatal environment critically modulate gene expression through reciprocal action with neurotransmitters, trophic factors, and hormones and their machinery. Accordingly, brain malformations can be due to environmental factors, genetic factors, or an interaction of both (Boxes 40-1 through 40-4).

This part of the chapter focuses primarily on the development of the neocortex. Detailed descriptions of the development of other CNS structures such as cerebellum can be found in texts by ten Donkelaar and colleagues[111] and Wang and Zoghbi.[121]

Neural Induction and Neurulation

During early stages of gastrulation, organizing centers produce inductive molecules that initiate genetic programs leading to the differentiation of the neural tissues from surrounding tissues.[108] Grafting experiments in amphibians have shown that the appearance of neural tissue depends on signals coming from mesodermic cells of the dorsal marginal zone (the Speeman organizing center) and that other signals deriving from this zone also allow the regionalization of the neuroectoderm along the rostrocaudal axis. Studies have identified some of the factors implicated in neural induction, including follistatin, noggin, Notch, dorsalin1, Wnt1, and Hedgehog.

Neurulation is the process by which neuroectodermal cells transform into a neural tube, which will differentiate into the brain and the spinal cord. Neurulation can be divided into four steps that overlap both in time and space: (1) neural plate formation, (2) neural plate modeling, (3) neural groove formation, and (4) closure of the neural groove to form the neural tube. In humans, the neural plate appears at the beginning of the third gestational week in the mediodorsal zone of the embryo, just ahead (in the rostrocaudal axis) of the Hensen node. The neural groove appears during the third gestational week. Neural tube closure starts at the beginning of the fourth gestational week, with the formation of the neural crests (which will give rise to dorsal root ganglia, Schwann cells, and cells of the pia and arachnoid). Neural tube closure begins in the region of the lower medulla and proceeds both rostrally and caudally.

The anterior neuropore closes at approximately 24 gestational days and the posterior neuropore closes at approximately 26 gestational days. This posterior site of closure is located around the lumbosacral level, and more caudal spinal cord is formed secondarily by a separate process involving canalization (4 to 7 gestational weeks) and retrogressive differentiation (seventh gestational week to after birth; giving rise to the ventriculus terminalis and the filum terminale). The neural tube is initially a straight structure. Before the closure of the posterior neuropore, the anterior part of the neural tube is shaped into three primary vesicles: the prosencephalon, the mesencephalon, and the rhombencephalon.

TABLE 40–1 Schematic Chronology of the Major Events During Human Neocortical Development

Neuroectoderm induction	3rd GW
Neurulation	3rd to end of 4th GW
Prosencephalic and hemispheric formation	5th-10th GW
Neuronal proliferation	10th-20th GW
Neuronal migration	12th-24th GW
Programmed neuronal cell death	28th-41st GW
Neurogenesis	15th-20th GW to ? postnatal months or years
Synaptogenesis	20th GW to puberty
Gliogenesis	20th-24th GW to ? postnatal years
Myelination	36th-38th GW to 2-3 postnatal years
Angiogenesis	5th-10th GW to ? postnatal years

GW, gestational week.

The prosencephalic phase and the formation of the hemisphere take place between 5 and 10 gestational weeks in humans.

CNS regionalization results from the combination of two mechanisms. Rostrocaudal regionalization creates transverse domains with distinct competences in the neural plate and tube,[57,106,123] whereas dorsoventral regionalization creates longitudinally aligned domains.[103] The combination of these two axes yields a grid-shaped pattern or regionalization.[101] Different genes involved in this regionalization have been identified. These include *BMP* (bone morphogenetic proteins), *PAX* (paired box genes), and *SHH* (sonic hedgehog) genes for the dorsoventral axis, and *HOX* (clustered homeobox-containing genes), *KROX20*, *FGF8* (fibroblast growth factor-8), *EN* (engrailed genes), *WNT*, *OTX* (homeobox genes homologous of the *Drosophila* orthodenticle gene), *EMX* (related to the "empty spiracles" gene expressed in the developing *Drosophila* head), and *DLX* (homeobox genes homologous to the distal-less genes of *Drosophila*) genes for the rostrocaudal axis (Fig. 40-1).

Neuronal Proliferation

There are no precise data concerning the number of neurons present in the brains of different mammalian species. In the human adult brain, estimates range from 3 billion to 100 billion neurons. Similarly, the precise proportion of glial cells is unknown, with a neuron-to-glia ratio estimated at between 1:1 and 1:10.

BOX 40–1 Environmental Factors and Maternal Conditions with Potential Impact on the Developing Brain

THERAPEUTIC DRUGS
Retinoic acid
Antithyroid drugs
Estroprogestative hormones, testosterone, and derivatives
Antimitotic drugs
Lithium and psychotropic drugs
Benzodiazepines and antiepileptic drugs

ADDICTION DRUGS
Tobacco
Caffeine
Ethanol
Cocaine
Opiates
Cannabis

PHYSICAL AND CHEMICAL AGENTS
Dioxins and heavy metals
Organic solvents
Ionizing radiation
Head trauma
Repeated shaking

MATERNAL FACTORS AND STATUS
Sex hormones
Catecholamines
Thyroid hormones
Diabetes mellitus
Peptides (vasoactive intestinal peptide)
Placenta and decidual hormones
Oxygen and hypoxia-ischemia
Hyperthermia

INFECTIOUS AGENTS
Herpes simplex I and II
Herpes zoster
Cytomegalovirus
Rubella virus
Parvovirus B19
Coxsackie virus, B group
Human immunodeficiency virus
Influenza virus
Benign lymphocytic meningitis virus
Toxoplasma gondii
Listeria monocytogenes
Syphilis

In some regions of the CNS, neuron production continues for the entire life span. This late neuronogenesis is clearly apparent in the olfactory bulb and the dentate gyrus. Its importance at the level of the neocortex, especially in physiologic conditions, remains to be demonstrated. In this context, production of neurons for the human neocortex is generally considered to be a phenomenon occurring during the first half of gestation.

The neocortex is composed of vertical units (neuronal columns): the number of neurons in a given unit seems stable

BOX 40–2 Major Etiologies of Human Holoprosencephaly

CHROMOSOMAL HOLOPROSENCEPHALY

Chromosome 13: trisomy, deletion or duplication of 13q, ring
Deletion 2p, duplication 3p, deletion 7q, deletion 21q
Triploidy

SYNDROMAL HOLOPROSENCEPHALY

Meckel syndrome
Varadi-Papp syndrome
Pallister-Hall syndrome
Smith-Lemli-Opitz syndrome
Velocardiofacial syndrome

NONSYNDROMAL GENETIC HOLOPROSENCEPHALY (SPORADIC OR MENDELIAN INHERITANCE)

SIX3: HPE2 locus on chromosome 2p21
SHH: HPE3 locus on chromosome 7q36
TGIF: HPE4 locus on chromosome 18p11.3
ZIC2: HPE5 locus on chromosome 13q32

ENVIRONMENTAL HOLOPROSENCEPHALY

Hypocholesterolemia
Retinoic acid
Ethanol

BOX 40–3 Classification of Human Congenital Microcephaly

PRIMARY GENETIC MICROCEPHALY

Micrencephaly vera and radial microbrain (autosomal recessive or X-linked for one locus):
- *MCPH1* (microcephalin)
- *MCPH5* (ASPM gene)
- *SLC25A19* (deoxynucleotide carrier)

Microcephaly with simplified gyral pattern (autosomal recessive):
- Normal or thin corpus callosum
- Agenesis of the corpus callosum

Microlissencephaly (MLIS) (autosomal recessive):
- With thick cortex (MLIS1 or Norman-Roberts syndrome)
- With thick cortex, brainstem and cerebellar hypoplasia (MLIS2 or Barth syndrome)
- With intermediate cortex (MLIS3)
- With mildly to moderately thick cortex (MLIS4)

MICROCEPHALY ASSOCIATED WITH OTHER BRAIN MALFORMATIONS

MICROCEPHALY AS PART OF A SYNDROME

Neu-Laxova syndrome
Seckel syndrome
Rubinstein-Taybi syndrome
Cornelia de Lange syndrome
Microcephalic osteodysplastic dwarfism

MICROCEPHALY ASSOCIATED WITH BIOCHEMICAL DISORDERS

MICROCEPHALY SECONDARY TO ENVIRONMENTAL FACTORS

Hypoxia-ischemia
Severe malnutrition
Maternal hyperphenylalaninemia and phenylketonuria
Ionizing radiation
Ethanol
Infections (cytomegalovirus, benign lymphocytic meningitis virus, *Toxoplasma gondii*)

throughout studied mammals and is constant throughout the different cortical areas (with the exception of the visual cortex). In contrast, the time necessary to produce the neocortical neurons of a given column progressively increases with increasing mammalian evolutionary complexity. Indeed, the period of neuronogenesis takes 6 days in mice whereas it takes 10 weeks in humans (gestational weeks 10 to 20, approximately). This period of neuronogenesis corresponds to the production of neurons from precursors present in the germinative neuroepithelium.

Administration of bromodeoxyuridine or tritiated thymidine, which are incorporated into DNA during the S phase of the mitotic cycle, has allowed the different parameters of the mitotic cycle and their evolution during the progression of neuronogenesis to be studied both in rodents and monkeys. In the pioneering model described by Caviness and collaborators,[23] which is based on the existence of a homogeneous population of precursors in the periventricular germinative neuroepithelium, the length of the total mitotic cycle progressively increases during the neuronogenetic interval (Fig. 40-2). This progressive increase in length is due to the progressive increase in length of G_1 phase, while G_2, M, and S phases remain constant. However, interference with the γ-aminobutyric acid (GABA)-ergic or glutamatergic systems in monkeys has been shown to modulate the length of S phase during this period. The second major contribution of these studies is to show that the proportion of daughter cells that reenters the mitotic cycle (G_1 phase) or leaves the cycle (postmitotic G_0 cells that are going to migrate to the cortex) is variable and depends on the stage of progression in the neuronogenetic interval. Therefore, in this model, at each step of the neuronogenetic interval, the periventricular neuroepithelium can be characterized by two variables: the length of G_1 phase and the fraction of daughter cells that will continue to divide. Although this model is based on the assumption that cell death is negligible in the germinative neuroepithelium, a report[15] suggests that a large part of the precursor cells die in the germinative neuroepithelium during the neuronogenetic interval. Also, the existence of a regionalized germinative neuroepithelium has been proposed,[93] where cell cycle parameters would depend on the location of the dividing cell. This regionalization would allow an early specification of the characteristics for the future cortical areas.

During the neuronogenetic interval, after the M phase of the mitotic cycle, daughter cells face a dual choice: to reenter the mitotic cycle (G_1) or to leave the cycle (G_0) and, by doing so, to become postmitotic for the rest of their lives. Some factors, like insulin-like growth factor type 1, fibroblast growth factor, or vasoactive intestinal peptide, stimulate mitoses of neuronal precursors, whereas factors like glutamate or GABA reduce the proliferation of these cells but do not push

BOX 40–4 Genes and Environmental Factors Identified in Human Neuronal Migration Disorders

GENES

FLN1 (filamin): X-linked periventricular heterotopia
LIS1: type I lissencephaly (generally sporadic) and Miller-Dieker syndrome (microdeletion 17p13.3)
DCX (doublecortin) or XLIS: X-linked double cortex syndrome (usually girls) and type I lissencephaly (usually boys)
RELN: autosomal recessive lissencephaly + cerebellar hypoplasia
PEX genes: Zellweger syndrome (autosomal recessive)

ENVIRONMENTAL FACTORS

Ethanol
Cocaine
Cytomegalovirus
Toxoplasma gondii
Ionizing radiation

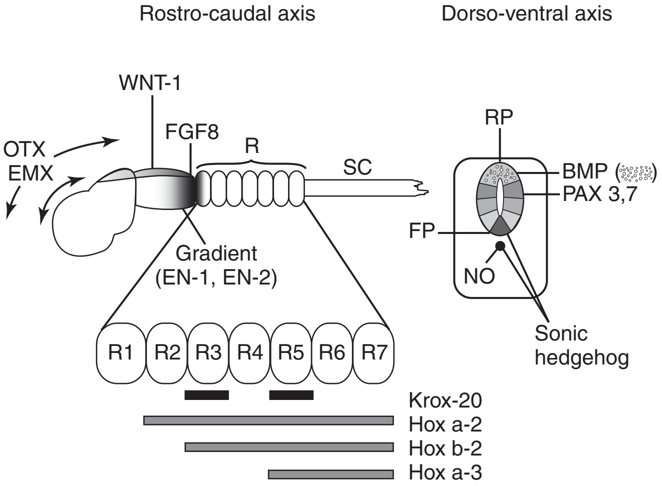

Figure 40–1. Schematic representation of some genes involved in the patterning of the rostrocaudal and dorsoventral axis of the central nervous system. FP, floor plate; NO, notochord; R, rhombomeres; RF, roof plate; SC, spinal cord. *(From Lagercrantz H, Ringstedt T: Organization of the neuronal circuits in the central nervous system during development,* Acta Paediatr *90:707, 2001, with permission.)*

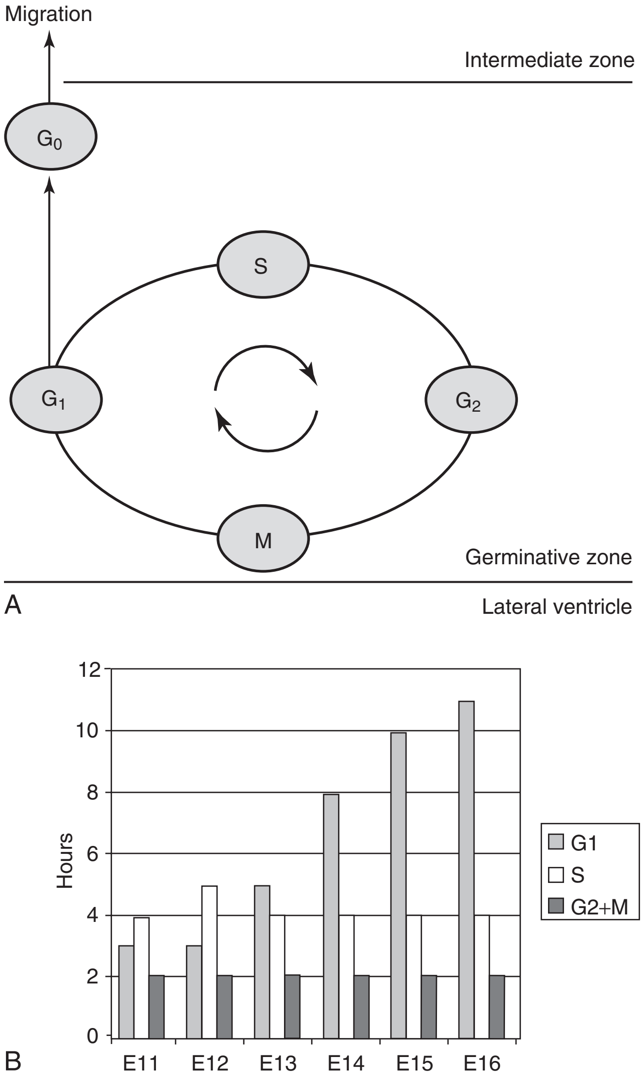

Figure 40–2. **A**, Schematic representation of the different phases of the mitotic cycle in the germinative neuroepithelium. Note the interkinetic movement of nuclei during the mitotic cycle: the relative position of the nucleus in the germinative zone is determined by the phase of the cycle. G_1, phase of protein synthesis; S, phase of DNA duplication; G_2, phase of protein synthesis; M, mitosis; G_0, postmitotic phase. **B**, Evolution of the length of the different phases of the mitotic cycle in the mouse germinative zone during the period of neuronogenesis (between embryonic days 11 and 16). During this interval, duration of the mitotic cycle increases from 8 hours up to 18 hours. This increased duration is secondary to a progressive increase in duration of G_1 phase.

these cells to become postmitotic. Very few factors have been described as capable of withdrawing precursor cells from the mitotic cycle. Pituitary adenylate cyclase-activating polypeptide seems to be one of these factors because it is able to prevent daughter cells from reentering the mitotic cycle and to initiate their migration to become cortical neurons.[73]

Neuronal Migration and Cortical Lamination

Neocortical neurons derive from the primitive neuroepithelium and migrate to their appropriate position in the cerebral mantle. In humans, migration of neocortical neurons occurs mostly between the 12th and the 24th weeks of gestation.[104] The first postmitotic neurons produced in the periventricular germinative neuroepithelium (ventricular zone) migrate to form a subpial preplate or primitive plexiform zone (Fig. 40-3). Subsequently produced neurons, which will form the cortical plate, migrate into the preplate and split it into the superficial molecular layer (layer I or marginal zone containing Cajal-Retzius neurons) and the deep subplate. Schematically, the

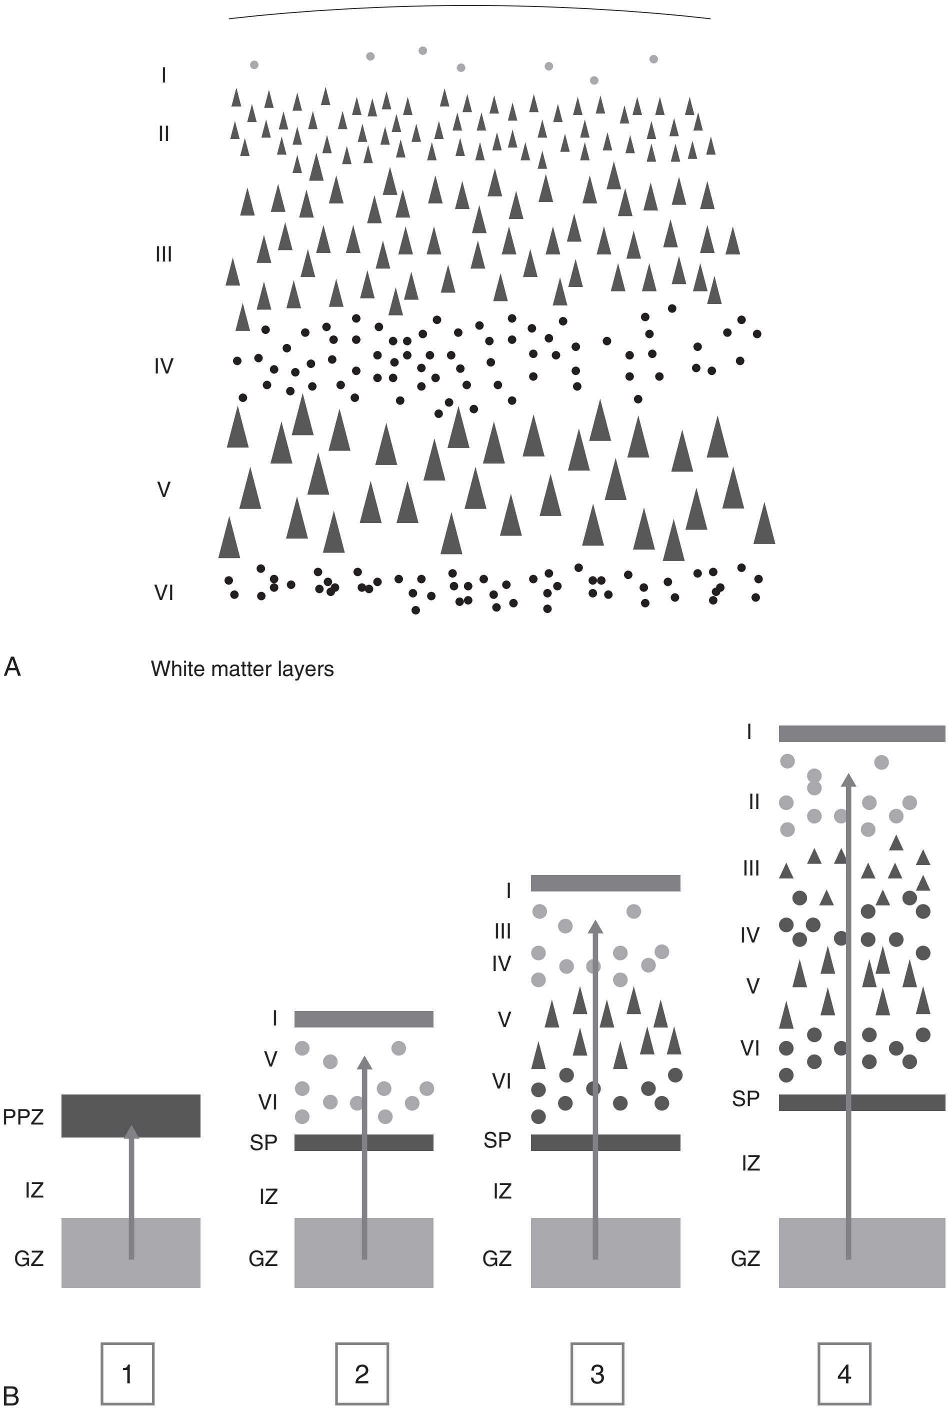

Figure 40–3. A, Schematic representation of the six layers of the mature mammalian neocortex. B, Schematic illustration of mammalian neocortical formation and neuronal migration. successive waves of migratory neurons pass the subplate neurons and end their migratory pathway below layer I, forming successively (but with substantial overlap) cortical layers VI, V, IV, III, and II (an inside-out pattern).

Neocortical migrating neurons can adopt different types of trajectories (Fig. 40-4)[43,95]:

1. A large proportion of neurons migrate radially, along radial glial guides, from the germinative zone to the cortical plate. Radial glia are specialized glial cells present in the neocortex during neuronal migration; these cells display a radial shape with a nucleus located in the germinative zone, a basal process attached on the ventricular surface, and a radial apical process reaching the pial surface (Fig. 40-5). Rakic[96] postulated that these radially arranged glial guides keep a topographic correspondence between a hypothesized protomap present in the germinative zone (ventricular and subventricular zones) and the cortical areas.
2. An important group of neuronal precursors initially adopt a tangential trajectory at the level of the ventricular or subventricular germinative zones before adopting a classic

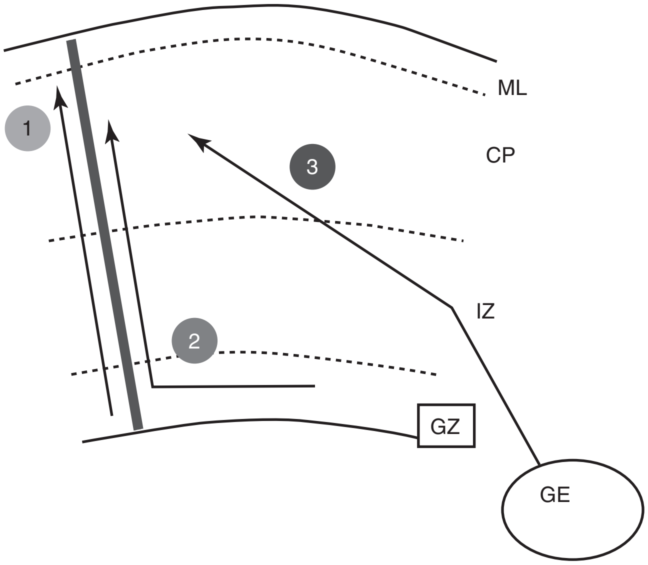

Figure 40–4. Schematic representation of the different migratory pathways adopted by neurons. **1**, Radial migration along radial glial cells of neurons originating from the periventricular germinative zone (GZ). **2**, Tangential migration in the germinative zone (GZ) followed by a radial migration along glial guides. **3**, Tangential migration in the intermediate zone (IZ) of neurons originating from the ganglionic eminence (GE). radial migrating pathway along radial glia. This tangential migration could permit some dispersion at the level of the cortical plate of neurons originating from a single clone in the germinative neuroepithelium, increasing the clonal heterogeneity within a given cortical area.

3. Tangentially migrating neurons have also been described at the level of the intermediate zone (prospective white matter). Most of these neuronal cells displaying a migrating pathway orthogonal to radial glia originate in the ganglia eminence. Most GABA-expressing interneurons seem to be produced by this mechanism.

Using time-lapse imaging of clonal cells in rat cortex over several generations, it was shown that neurons are generated in two proliferative zones by distinct patterns of division.[83] Neurons arise directly from radial glial cells in the ventricular zone and indirectly from intermediate progenitor cells in the subventricular zone. Furthermore, newborn neurons do not migrate directly to the cortex; instead, most exhibit distinct phases of migration, including a phase of retrograde movement toward the ventricle before migration to the cortical plate.

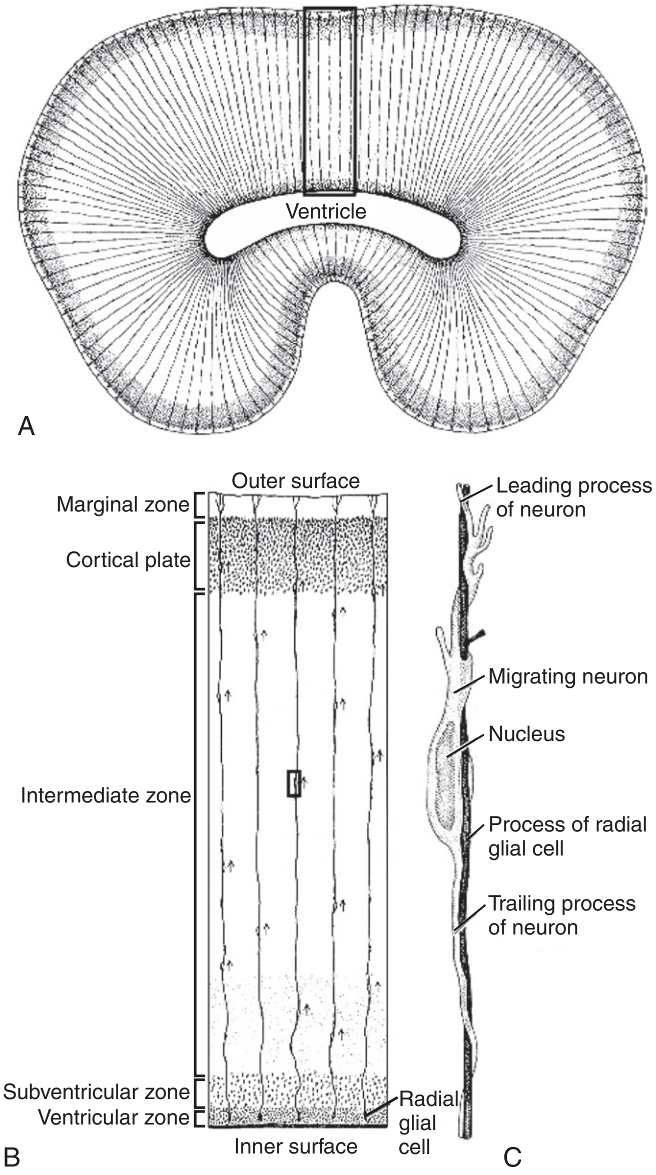

Figure 40–5. **A**, Schematic representation of the immature primate brain. **B**, Illustration of section (box in **A**) through the primate brain with the laminar organization of the immature brain, with ventricular, subventricular, intermediate zone, cortical plate, and marginal zone, and the arrangement of radial glial fibers illustrated in magnification. **C**, Three-dimensional reconstruction of a migrating neuron (magnified box in **B**) with radial fiber from radial glial cell having their origin in the ventricular zone and their relations to the migrating neuron. *(Modified from Rakic P: Mode of cell imigration to the superficial layers of fetal monkey neocortex.* J Comp Neurol *145:66, 1972.)*

The phenotype of radial glia seems to be determined both by migrating neurons and by intrinsic factors expressed by glial cells. Among the latter, the transcription factor Pax6, which is specifically localized in radial glia during cortical development, is critical for the morphology, number, function, and cell cycle of radial glia. From the appearance of the cortical plate, the radial glial fibers are grouped in fascicles of five to eight fibers in the intermediate zone.[61] The final cortical location of the neurons, which could be determined by the guiding glial fascicle, partly determines the connections the neuron will be able to establish. The fascicles of glial fibers, filled with glycogen, could also provide the energy supply for migrating neurons, which are distant from developing blood vessels.

The ontogenic unit comprising the radial glial fascicle is very similar in the mouse, rat, hamster, cat, and human.[45] Because this glial unit is constant throughout the mammalian species studied, it could represent the basic developmental module of the developing cortex: the unit remains stable while the number of adjacent units gradually increases to permit brain expansion in the evolution of mammalian species. Knowledge of the genetic and environmental factors that control the organization, number, and function of these glial fascicles could, therefore, improve understanding of cortical development and evolution of the brain.

Studies over the last decade have identified several molecules involved in the control of neuronal migration and in targeting neurons to specific brain regions.[14,26] These molecules can be divided into four categories (Fig. 40-6):

1. Molecules of the cytoskeleton that play an important role in the initiation and progression (extension of the leading process and nucleokinesis) of neuronal movement. Initiation controlling molecules include Filamin-A (an actin-binding protein involved in periventricular nodular heterotopia) and Arfgef2 (ADP-rybosylation factor GEF2, which plays a role in vesicle trafficking and is involved in periventricular heterotopia combined with microcephaly). Progression controlling molecules include doublecortin (Dcx, a microtubule-associated protein [MAP] involved in double cortex and lissencephaly), Lis1 (a MAP and dynein regulator involved in isolated type 1 lissencephaly and Miller-Diecker syndrome), and other molecules that are associated with migration defects in transgenic mice but that have not yet been associated with human disorders (phosphatase inhibitor 14-3-3epsilon, MAP1B, MAP2, and Tau).
2. Signaling molecules, which play a role in lamination. These molecules include the glycoprotein Reelin (involved in lissencephaly and cerebellar hypoplasia in humans and in the Reeler mouse mutant characterized by an inverted cortex) and other proteins generally associated with inverted cortex in transgenic or mutant mice, but which have not yet been associated with human disorders such as adaptor protein Disabled-1 (Dab1), ApoE receptor 2 (Apoer2), very low density lipoprotein receptor (Vldlr), two Reelin receptors, serine-threonine kinase Cdk5 (cyclin-dependent kinase 5), activator of Cdk5 p35, Brn1/Brn2, and transcriptional activators of Cdk5 and Dab-1.
3. Molecules modulating glycosylation which seem to provide stop signals for migrating neurons. These molecules include POMT1 (protein *O*-mannosyltransferase associated with Walker-Warburg syndrome), POMGnT1 (protein *O*-mannose beta-1,2-N-acetylglucosaminyltransferase involved in muscle-eye-brain disease), Fukutin (a putative glycosytransferase involved in Fukuyama muscular dystrophy), and focal-adhesion kinase (Fak involved in migration disorder in transgenic mice). These three human

This scheme illustrates the cross-talk between different groups of molecules including cytoskeletal proteins, signaling molecules of the Reelin pathway, NMDA receptor-mediated pathway, and peroxisome-derived factors.

diseases comprise type 2 lissencephaly (cobblestone lissencephaly).

4. In addition to these three major groups of molecules, other factors have been shown to modulate neuronal migration, including neurotransmitters (glutamate and GABA),[10,12,75] trophic factors (brain-derived neurotrophic factor BDNF and thyroid hormones),[20] molecules deriving from peroxisomal metabolism, and environmental factors (ethanol and cocaine).

The application of diffusion-weighted magnetic resonance imaging (MRI) or diffusion tensor MRI to the evaluation of developing brain has opened up the possibility to study some of these developmental events in vivo. Quantitative indices derived from the diffusion tensor allow measurement of apparent diffusion and diffusion anisotropy, which ultimately depend on microstructural tissue development. Several different diffusion tensor imaging (DTI) parameters are available in this assessment. These include the three diffusion tensor eigen values ($\lambda 1$, $\lambda 2$, $\lambda 3$, which represent diffusion along the three tensor principal axes), the mean diffusivity (D_{av}) or apparent diffusion constant (ADC), and a mathematical measure of anisotropy, which describes the degree to which water diffusion is restricted in one direction relative to all others. Diffusion tensor MRI was used to study cortical development in human infants ranging from 26 to 41 weeks' gestational age; apparent diffusion of water in cortex was maximally anisotropic at 26 weeks' gestational age and declined to zero by 36 weeks' gestational age.[76] During this period, the major eigenvector of the diffusion tensor in cerebral cortex is oriented radially across the cortical plate. Vector maps illustrate diffusion anisotropy and direction of the major diffusion eigenvector. In the case of cortical gray matter, the vectors are oriented radially, consistent with the orientation of the radial glial fibers (Fig. 40-7).[76] Anisotropy changes are different in early intracortical maturation, where changes in fraction anisotrophy (FA) are mainly due to changes in $\lambda 1$[28] confirmed also by studies in the developing rat brain.[51,107] One study on human fetal brain has shown that cortical anisotropy increases from 15 weeks' gestation to approximately 26 weeks' gestation and then shows a gradual decline to 32 weeks' gestation.[47] The increase of anisotropy in this time period coincides with active neuronal migration along the radial glial scaffolding, whereas the decrease coincides with the phase of neocortical maturation with transformation of the radial glia into the more complex astrocytic neuropil.

The use of new, ultrafast MRI sequences such as multiplanar, single-shot, fast spin-echo T2-weighted images provides high-resolution images of the fetus in utero with imaging times of less than 1 minute.[2] The normal MRI pattern of fetal brain maturation from 13 weeks' gestation has been described, documenting the presence of the primary sulci and the insula by 15 weeks' gestation. Operculization of the insula begins by 20 weeks' gestation and all the main sulci, except the occipital sulci, are present by 28 weeks' gestation.[2] From 28 weeks' gestation there is mainly an increase in secondary and tertiary sulcal formation. From 23 to 28 weeks in vivo[41] and from 15 weeks in vitro,[19,27] the typical multilayer pattern of the cerebral parenchyma can be observed with the innermost hyperintense signal (T1-weighted MRI) of the germinal matrix (Fig. 40-8). The five-layer pattern of the fetal forebrain, including the layers of neuroblast formation and migration, could be identified at 16 to 18 weeks' gestation in postmortem fetal brains.[27] During the last trimester, the gyri and sulci already formed become more prominent and more deeply infolded, with subsequent development of secondary and tertiary gyri at 40 to 44 weeks of gestational age (Fig. 40-9).

Komuro and Rakic[64] first reported that specific inhibitors of the N-methyl-D-aspartate (NMDA) glutamate receptor subtype slowed down the rate of in vitro neuronal migration. GABA is also involved in neuronal migration modulation

because it stimulates, in tissue culture, neuronal migration through calcium-dependent mechanisms.[11] Growth factors also have been implicated in the control of neuronal migration. Intraventricular injection of neurotrophin-4 or overexpression of brain-derived neurotrophic factor produces heterotopic accumulation of neurons in the molecular layer (layer I), mimicking some aspects observed in human status verrucosus deformans.

Central Nervous System Organization

SUBPLATE NEURONS

As mentioned previously, subplate neurons constitute a distinct structure during neocortical development.[66] Neurons of the subplate are generated at approximately the seventh week of gestation, and the subplate is generated from the preplate at approximately 10 gestational weeks. This structure localized beneath the neocortical plate reaches its maximal thickness between 22 and 36 gestational weeks. The subplate is present in preterm neonates but has disappeared in full-term neonates. Some authors have suggested that these neurons disappear by apoptosis, whereas others have suggested that they are incorporated into layer VI of the mature neocortex.

Subplate neurons express different neurotransmitters, neuropeptides, and growth factors, receive synapses, and make connections with cortical and subcortical structures. These neurons play several important roles during brain development: (1) they produce axons for the internal capsule that will serve as guiding axons for axons originating from neurons in layers V and VI; (2) between 25 and 32 gestational weeks, they produce axons for the corpus callosum; (3) they act as a waiting zone for thalamocortical axons (with which they establish synapses) before they invade the cortical plate and reach layer IV. This waiting zone is necessary for appropriate target selection by thalamocortical afferents.

The subplate neurons can be lesioned or destroyed in preterm neonates with periventricular white matter lesions.[102] These data have been recently substantiated in animal models of periventricular white matter damage (see Part 2 of this chapter).[77]

MRI has been used to visualize the developmental evolution of the subplate zone and other laminar compartments of the fetal cerebral wall between 15 and 36 weeks' gestation.

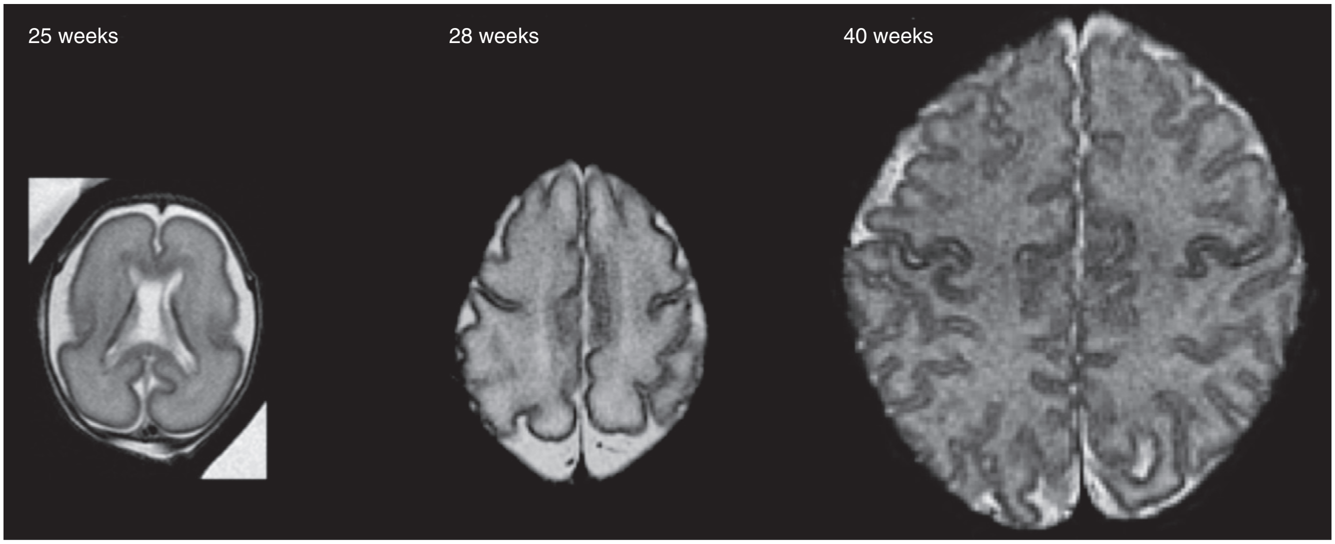

Figure 40–9. Cortical folding illustrated from 25 weeks' to 40 weeks' gestation by in vivo MRI. T2-weighted images at 25, 28, and 40 weeks' gestational age.

The combination of MRI and histochemical staining of the extracellular matrix enabled selective visualization of the subplate zone in the developing human brain. The tissue elements of the subplate zone are embedded in an abundant, very hydrophilic, and transient extracellular matrix that is most likely responsible for the low signal intensity on T1-weighted MRI in Figure 40-10 and the slightly higher signal intensity on T2-weighted MRI as seen in vivo at 26 weeks (Fig. 40-11).

AXONAL AND DENDRITIC GROWTH

When neurons near their final destination, they start to produce axons and dendrites, allowing connection with distant cerebral structures. This ontogenic step occurs largely, but

Figure 40–10. See color insert. The cerebral wall displays five laminar compartments of varying MRI signal intensity (**B**), which partly correspond to laminar compartments delineated on Nissl-stained (**A**) and histochemical (**C**) sections. Starting from the ventricular surface, these laminar compartments are as follows: The ventricular zone (germinal matrix) of high MRI signal intensity, which corresponds to the highly cellular ventricular zone in Nissl-stained sections and, therefore, is marked with number 1 (1 in **D**). The periventricular zone of low MRI signal intensity, which largely corresponds to the periventricular fiber-rich zone (2 in **D**). The intermediate zone of moderate MRI signal intensity, which encompasses both the subventricular cellular zone and the fetal white matter (3 and 4 in **D**). The subplate zone of low MRI signal intensity, which closely corresponds to the compartment marked with 5 in Nissl-stained section (5 in **D**) and acetylcholinesterase-stained section (5 in **C**); therefore it is marked with 5 on MR images (5 in **B**). The cortical plate of high MRI signal intensity, which closely corresponds to the compartment marked with 6 on Nissl-stained sections (6 in **D**) but on MR images cannot be separated from the marginal zone (7 in **D**); therefore, it is always described on MR images as a band of high signal intensity situated above the subplate zone. *(From Kostovic I, et al: Laminar organization of the human fetal cerebrum revealed by histochemical markers and magnetic resonance imaging,* Cereb Cortex *12:536, 2002, with permission.)*

not exclusively, during the second half of gestation and extends into the postnatal period. For example, evoked visual potentials can be produced as early as 24 to 27 gestational weeks in human neonates, confirming the existence of an established wiring at this early developmental stage.

Growing axons have to find their path through developing structures to reach their target. In this process, growing axons, and in particular their distal tip, called the *growth cone*, are helped by several mechanisms:

1. The transcriptome of each neuron contains information determining the types of connections this neuron can establish.
2. Target neurons or neurons on the pathway of growing axons secrete or express on their membranes chemoattraction or chemorepulsion factors that interact with receptors present on growth cones, resulting in attraction or repulsion of these axonal growth cones. Several ligand-receptor families have been described, including netrin, slit, comm, robo, semaphorin, cadherin, and ephrin receptors.[71] The interaction between these different ligands and receptors leads to changes in calcium levels in the growth cones, which seem to play a key role in the resulting behavior of the growth cone.
3. Neurotransmitters and trophic factors are liberated that will favor or inhibit the extension of the growing axons expressing the corresponding receptor.
4. Growth cones can interact with various glycoproteins of the extracellular matrix that act as guiding cues.
5. At early stages of brain development, distances separating structures are rather small, facilitating the navigation of growth cones. These first-produced axons, called *pioneer axons*, serve as guides for later-produced axons, when distances between structures are significantly larger.

As for neuronal production, some axonal projections are produced in excess, connecting too many structures or neurons. This initial phase is followed by a regressive phase where redundant or misconnected axons are eliminated or retracted, allowing the emergence of adequate and functional connections. This balance between the maintenance or the elimination of axons is regulated by different mechanisms. Obviously, the survival of the neuron is determinant in this decision. Furthermore, competition for available trophic factors interacts with the genome to modulate this balance.[21] Also, electrical activity is a key determinant for the maintenance of axons. Accordingly, in utero and especially postnatal stimuli and experiences significantly shape the developing brain by modulating the maintenance or elimination of some axons.[24]

Some callosal connections, some "feedback" intracortical connections, and some corticofugal projections (such as the motor pathway) seem to be examples of connections largely under the control of this "overproduction-elimination" principle and therefore are highly dependent on the environment.[56] In contrast, some "feedforward" intracortical connections seem to be more genetically predetermined and therefore less susceptible to environmental cues.[92]

Studying white matter development with in vivo imaging was largely impossible before the advent of advanced MR techniques, with diffusion imaging being of particular interest in the assessment of the white matter microstructure. Diffusion characteristics differ between pediatric and adult human brain in two primary ways. First, apparent diffusion coefficient (ADC) values are higher for pediatric brain than adult. Second, ADC maps of pediatric brain show contrast between white and gray matter, with the ADC values for white matter being higher than those for gray. The precise cause of the decrease in ADC with increasing age is not known, although it has been postulated that the rapid decrease observed between early gestation and term is due to the concomitant decrease in overall water content. Brain water content decreases dramatically with increasing gestational age. As it does, structures that hinder water motion (e.g., cell and axonal membranes) become more densely packed, which further restricts the motion of the remaining water. The use of diffusion tensor MRI has allowed visualization of early white matter connectivity (Fig. 40-12) with demonstration of interhemispheric callosal fibers in the nonmyelinated stage at 28 weeks of gestation. During white matter development, decreases in diffusion are observed principally in $\lambda 2$ and $\lambda 3$ (and much less in $\lambda 1$), which reflect changes in water diffusion perpendicular to white matter fibers and may indicate changes due to premyelination (change of axonal width) and myelination.[40,80,87]

Relative anisotropy values for white matter areas are relatively low in newborns and increase steadily with increasing age.[81] They are particularly low for preterm infants.[54] This

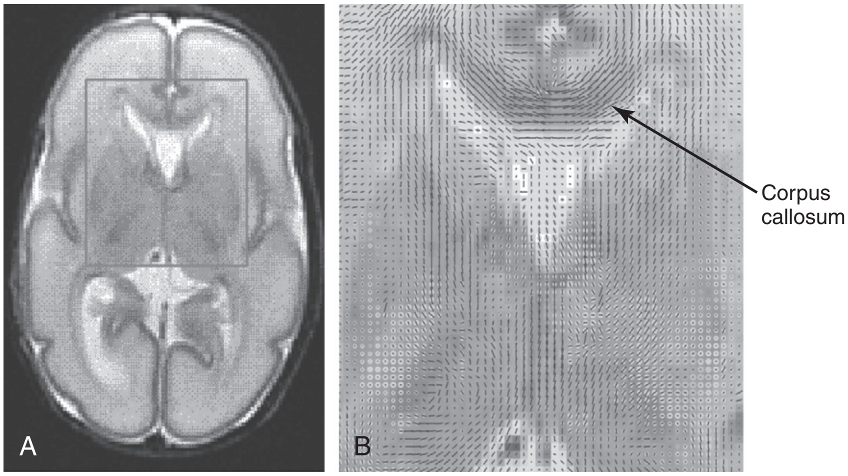

Figure 40–12. See color insert. **A**, Anatomic axial T2-weighted MRI. **B**, Diffusion tensor vector maps for the regions indicated by the box in **A**, showing nonmyelinated interhemispheric fiber connections in the corpus callosum at 28 weeks' gestational age. The blue lines represent the in-plane fibers, the out-of plane fibers are shown in colored dots ranging from green to red. (*Hüppi PS, et al: Microstructural development of human newborn cerebral white matter assessed in vivo by diffusion tensor magnetic resonance imaging,* Pediatr Res *44:584, 1998, with permission.)*

increase has been attributed to changes in white matter microstructure that accompany the "premyelinating state."[122] This state is characterized by a number of histologic changes, including an increase in the number of microtubule-associated proteins in axons, an axon caliber change, and a significant increase in the number of oligodendrocytes. It is also associated with changes in the axonal membrane, such as an increase in conduction velocity and changes in Na^+/K^+-adenosine triphosphatase activity. Myelination then further increases relative anisotropy values. Although myelin accounts for much of the change in relative anisotropy, diffusion anisotropy is present under any circumstance in which the cytoarchitecture of the tissue is arranged in such a way as to lead to greater hindrance of water motion in one direction compared with others.

Making proper connections through white matter structures is probably one of the determining factors for further cortical organization. One major hypothesis for the morphogenetic mechanism of cortical folding is based on mechanical tension along axons in the white matter.[114] A striking increase in cerebral cortical volume accompanies the axonal and dendritic growth described previously. That this growth is particularly rapid between approximately 28 and 40 weeks' gestational age has been shown by quantitative three-dimensional MRI techniques with use of postacquisition image analysis. Volumetric analysis of MRI data sets is achieved by segmentation of the imaged volume into tissue types depending on their difference in signal intensity, followed by three-dimensional renderings. Overall brain volume more than doubles between 28 and 40 weeks' gestation, and cortical gray matter volume increases fourfold in the same period.[55] This increase is thought to relate primarily to neuronal differentiation rather than to an increase in the total number of neurons. Cortical surface, changing from smooth, lissencephalic to highly convoluted, increases fivefold between 28 and 40 weeks' gestation (Fig. 40-13).

So far, several hypotheses have been put forward on the mechanisms that underlie the folding process during development, but the potential influence of genetic, epigenetic, and environmental factors is still poorly understood. According to postmortem observations of fetal brains,[36] the primary folds would form in a relatively stable spatiotemporal way during intrauterine life depending on physical constraints

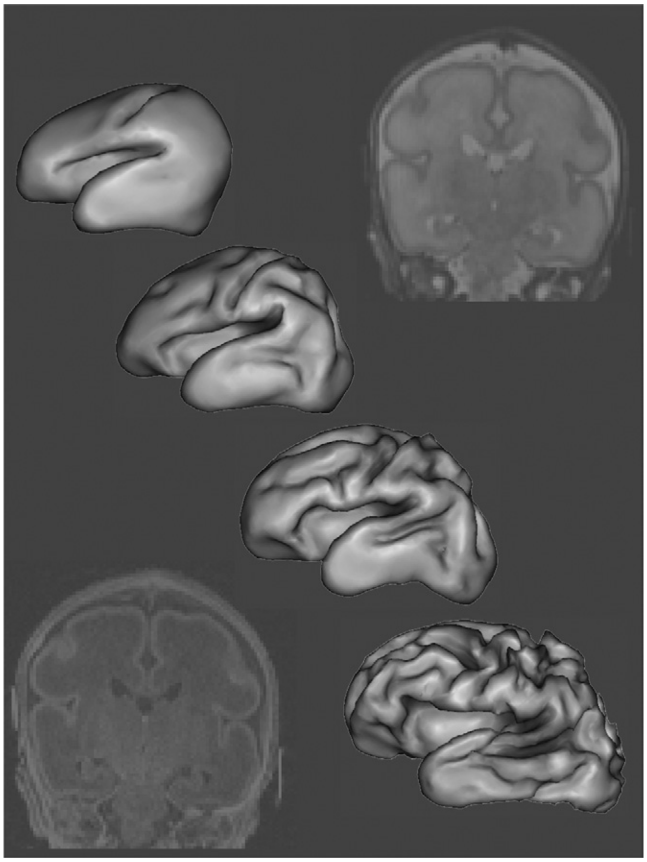

Figure 40–13. See color insert. External and internal brain surface at from 26 to 36 weeks' gestation illustrated by three-dimensional models generated from magnetic resonance imaging, which illustrates timing of regional cortical folding and permits quantitative measures of surface and sulcation index. (*Images reconstructed by specialized image analysis software, courtesy of Dubois J, Benders M, Cachia A, et al: Mapping the early cortical folding process in the preterm newborn brain,* Cereb Cortex *18:1444, 2008.)*

and mechanical factors.[97] An attractive theory suggests that the specific location and shape of sulci are determined by the global minimization over the brain of the viscoelastic tensions from white matter fibers connecting cortical areas.[48,49] This may explain why specific abnormalities in the sulcal pattern are observed in certain brain developmental disorders that are the result of subtle impairments in the neuronal migration and the set-up of corticocortical connections.[94,115] The emergence of the cortical foldings in the preterm newborn brain was recently studied by applying dedicated postprocessing tools to high-quality MR images acquired shortly after birth over a developmental period critical for the human cortex development.[33] Through the three-dimensional reconstruction of the developing inner cortical surface, a sulcation index was derived and allowed measurement of variations with age, gender, and presence of brain lesions and mapped the individual sulci appearance, highlighting early interhemispherical structural asymmetries that may be related to the cortical functional specialization of the brain. Females have lower cortical surface and smaller volumes of cortex and white matter than males, but equivalent sulcation. The highest sulcal index is found in the central region, followed by the temporoparieto-occipital region, with the lowest sulcation index in the frontal region, which confirms that the medial surface folds before the lateral surface and that the morphologic differentiation of sulci begins in the central region and progresses in an occipitorostral direction. Such spatiotemporal differences in brain maturation have been described in detail in older children through the analysis of cortical volume and thickness changes.[38] In particular, occipital regions grow much faster than prefrontal regions in newborns born at term,[39] and higher-order association cortices mature only after lower-order somatosensory and heterotopia visual cortices.[109]

The right hemisphere presents gyral complexity earlier than the left, which is particularly evident at the level of the superior temporal sulcus, which parallels early functional competence in response to auditive stimuli in newborns. Preterm birth may be responsible for the delay that we observed in sulci appearance in comparison with postmortem and fetal studies, in that both cortical volume[58] and surface area[1] of extremely preterm infants imaged at term equivalent age are decreased and less complex than in normal infants, and this impairment seems to increase with decreasing gestational age at birth.[62] Furthermore, preterm infants with intrauterine growth restriction had more pronounced reduction of volume in relation to surface area and increased sulcation with resultant changes in cortical thickness, which correlated with impaired behavioral functions.[32]

SYNAPTOGENESIS

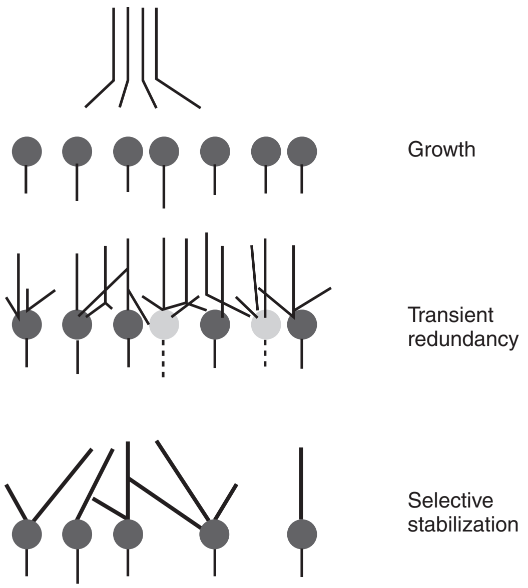

Figure 40–14. Schematic representation of the epigenetic hypothesis based on selective stabilization of synapses. Spontaneous or evoked activity of developing neuronal networks controls the selective elimination of redundant synapses formed during the transient phase of synaptic redundancy. *(Adapted from Changeux JP, Danchin A: Selective stabilisation of developing synapses as a mechanism for the specification of neuronal networks,* Nature *264:705, 1976.)*

The concept of synaptic stabilization (with the elimination of nonstabilized synapses) has been proposed.[25,34] During brain development, there are successive waves of overproduction of labile synapses, inducing redundant connections produced in a relatively random manner (Fig. 40-14). This step is under tight genetic control. Each wave of overproduction is followed by a period of stabilization of synapses that have a functional meaning and elimination of redundant or meaningless synapses. This period of stabilization and elimination is highly influenced by environmental stimuli and experience. In this model, a moderate increase in the number of genes would induce a richer substrate on which the environment could produce a more complex network. Neuronal activity-mediated glutamate release induces a postsynaptic calcium influx at the level of NMDA receptors. Calcium changes lead to production of trophic factors such as brain-derived neurotrophic factor, which stabilize labile synapses, protecting them against elimination. Nitric oxide, which is rapidly produced after glutamate binding to its NMDA receptor, is another key player in synaptic stabilization and plasticity. This model of synaptic stabilization and elimination does not exclude the existence of an instructive process where synaptic connections are adequately established right away.

In monkey occipital neocortex, five successive waves of synaptogenesis have been described.[18] Based on data obtained in human occipital cortex,[71] the following timetable for humans is proposed (Fig. 40-15): (1) a first phase starting approximately 6 to 8 weeks of gestation and limited to lower structures like the subplate; (2) a second phase starting after 12 to 17 weeks with relatively few synapses produced in the cortex (contacts on the dendritic shafts); (3) a third phase starting around midgestation and ending approximately 8 months after birth; this phase is characterized by an estimated rate of 40,000 new synapses per second in the monkey; (4) a fourth phase lasting until puberty and also characterized by a high rate of synapse production; and (5) a last phase extending until late adulthood but somewhat hidden by the intense loss of synapses characterizing these ages. Experimentally, the first two phases are not affected by lack of sensory stimuli. The third phase partially depends on this sensory input, whereas the fourth phase is highly dependent on sensory input and experience.

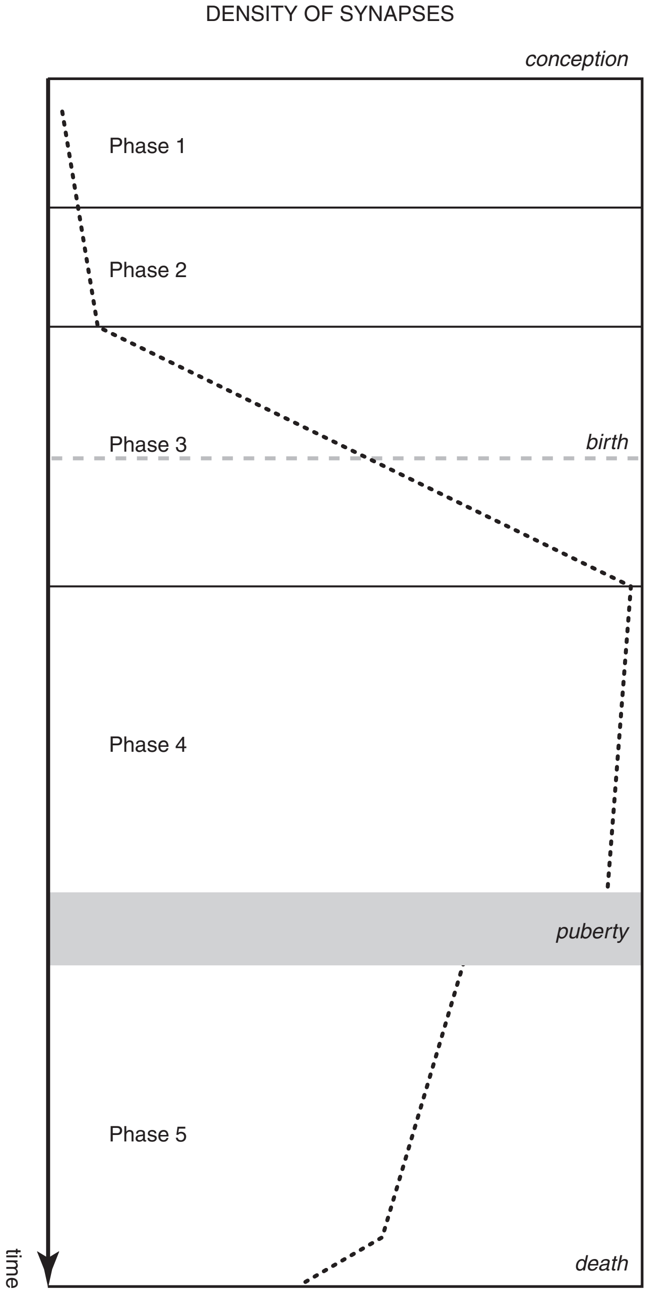

Figure 40–15. Schematic representation of the synaptic density in the visual cortex of the macaque monkey. *(From Bourgeois JP: Synaptogenesis, heterochrony and epigenesis in the mammalian neocortex,* Acta Paediatr Suppl *422:27, 1997.)*

Current understanding of the mechanisms of synaptogenesis and of synaptic stabilization raises numerous questions in neonatal medicine and pediatric neurology. Very preterm infants are a typical example of such an issue:

1. What are the effects of environmental modifications of preterm birth on synaptic stabilization?
2. What are the influences (positive or negative) of too early sensory stimuli for synaptogenesis?
3. What are the effects on the synaptic equipment of drugs that interfere with the glutamatergic or the nitric oxide system?

PROGRAMMED CELL DEATH

Depending on brain area, between 15% and 50% of the initially formed neurons will be eliminated by a physiologic process called *programmed cell death,* or *apoptosis*. Approximately 70% of these neurons that are destined to disappear seem to die between 28 and 41 gestational weeks.[13]

Programmed cell death is a complex mechanism that involves a balance between death and trophic signals, death and survival genetic programs, and effectors and inhibitors of cell death (Fig. 40-16).[78,116] Under the influence of a combination of exogenous and endogenous factors, genetic programs are activated (hence the name, “programmed cell death”) that are able to overcome the natural defenses of the neuron. The cell eventually dies and is rapidly removed by phagocytosis performed by neighboring glial cells. In this process, activation of the cascade of caspases (proteolytic enzymes) is a key step leading to DNA fragmentation and neuronal cell death. The caspase pathway can be activated by intrinsic and extrinsic mechanisms. The intrinsic mechanism or mitochondrial-dependent pathway is triggered by cytochrome C release by mitochondria and is controlled by members of the Bcl-2 family, whereas the extrinsic pathway is triggered by activation of death receptors, a subgroup of the tumor necrosis factor receptor superfamily. Neuronal apoptosis can be also triggered by a caspase-independent pathway involving AIF (apoptosis-inducing factor) release from mitochondria.

Electrical activity seems to be a critical factor for neuronal survival. During the period of brain growth spurt in rodents, administration of drugs that block electrical activity leads to a dramatic exacerbation of neuronal cell death in different brain areas. These drugs include NMDA receptor blockers (MK-801 or ketamine), GABA-A receptor agonists such as classic antiepileptic drugs (phenytoin, phenobarbital, diazepam, clonazepam,

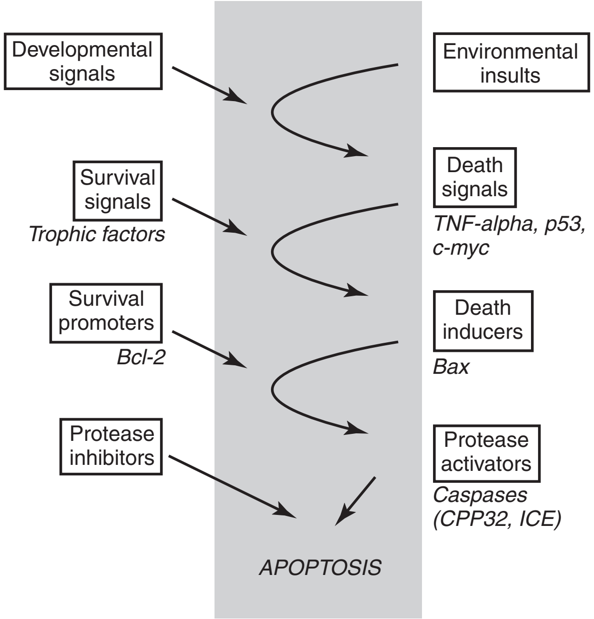

Figure 40–16. Schematic representation of the molecular cascade leading to neuronal apoptosis and showing the balance between pro-survival (left side) and pro-death (right side) factors.

vigabatrin, or valproic acid), and anesthetics (combination of midazolam, nitrous oxide, and isoflurane).[86] These effects on neuronal cell death are mimicked by acute administration of ethanol, which blocks NMDA receptors and activates GABA-A receptors. Although the mechanism is unknown, the systemic injection of a combination of sulfites (which are present in the excipient of some commercially available preparations of injectable glucocorticoids and vasoactive amines) and dexamethasone to newborn mouse pups led to an exacerbation of programmed neural cell death both in the neocortex and basal ganglia.[9,103]

Postnatal systemic steroid therapy had been widely used for chronic lung disease in the preterm infant until follow-up studies indicated higher rates of cerebral palsy and of subnormal (less than 70) cognitive function in steroid-treated infants (see Chapter 44, Part 7). Quantitative MRI studies have indicated a possible origin of these functional deficits by showing marked reduction of cortical gray matter volume after repetitive antenatal and postnatal steroid treatment.[79,82] Different roles have been attributed to programmed cell death, although final proofs are still lacking. These comprise elimination of "sick" neurons; increase of neuronal diversity by eliminating redundant neurons; and competition for trophic factors with elimination of neurons that have lower access to these trophic factors.

GLIAL PROLIFERATION AND DIFFERENTIATION, AND MYELINATION

Glia is composed of three types of cells: astrocytes, oligodendrocytes, and microglia (brain macrophages).

Astrocytes

Neocortical astrocytes have a dual origin (Fig. 40-17).[46] After the end of neuronal migration, radial glial cells (which are glial cells specialized in the guidance of migrating neurons) transform into astrocytes, which are found mainly in the deep cortical layers and underlying white matter. In addition, the periventricular germinative zone produces, after the end of neuronal production, astrocytic precursors that will migrate mostly into the superficial neocortical layers.

The presence of low-intensity periventricular bands in the white matter on T2-weighted MRI has been recorded in studies of premature infants, predominantly less than 30 weeks' gestational age. These bands are thought to represent populations of migrating radial glial cells based on their position and on correlative neuropathologic data.[8,26] The presence of these bands on T2-weighted MRI is therefore thought to be a marker of normal brain development.

Transformation of radial glia into astrocytes involves an autophagic digestion of apical processes and a nuclear translocation from the germinative neuroepithelium toward the white matter. Molecular mechanisms controlling this transformation remain unknown. In vitro, it was shown that neurons are necessary to maintain the radial phenotype of these glial cells.

In human neocortex, this astrocytic proliferation probably starts at approximately 24 weeks of gestation, with a peak at approximately 26 to 28 weeks. The final stage of astrocyte production is not known, but one might assume that the bulk of astrocyte production is completed by the end of normal gestation. However, it is important to remember that astrocytes retain the capability to divide throughout their life span. This peak of astrocyte production at approximately 26 to 28 weeks might be particularly important for preterm neonates. Indeed, astrocytes play several important roles during brain development, including axonal guidance, stimulation of neuron growth, synaptic formation, transfer of metabolites between blood vessels and neurons (magnetic resonance spectroscopy [MRS] results), establishment of

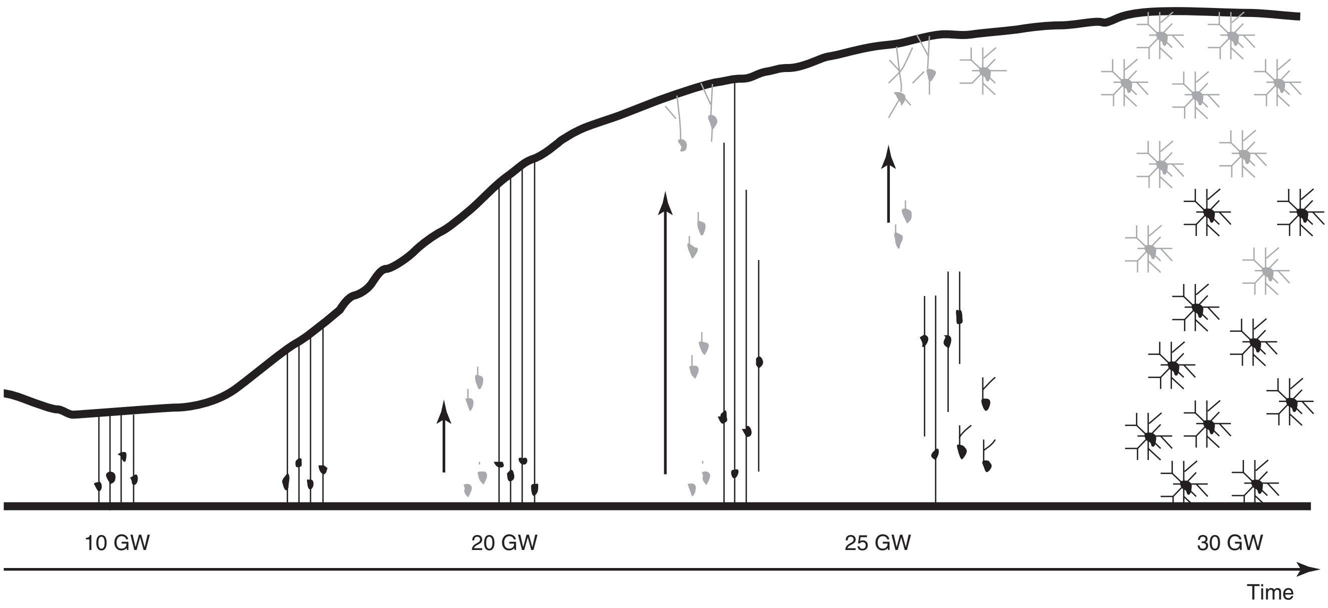

Figure 40–17. Schematic representation of the dual origin of neocortical astrocytes in human fetuses. Astrocytes destined to the white matter and deep cortical layers derive from the progressive transformation of radial glial cells (black cells), whereas most astrocytes destined to the more superficial cortical layers derive from precursors that migrate from the germinative neuroepithelium (gray cells). GW, gestational weeks. Arrows indicate migrating astrocytes.

scaffolding structures, production of extracellular matrix components, production of trophic factors, neuronal survival, myelination, and participation in the blood-brain barrier. For example, experimental transient blockade of astrocyte production in the rodent neocortex leads to increased neuronal programmed cell death and long-term changes in neocortical synaptic equipment.[125]

One of the essential contributors to progress in the noninvasive detection of tissue metabolism and in vivo biochemistry in recent years has been ^{1}H-MRS, which gives specific chemical information on the biochemistry of numerous intracellular metabolites (Fig. 40-18). Neurochemistry has particularly benefited from this technique, in that there is the possibility of detecting cerebral metabolites in vivo in otherwise inaccessible tissue. Astrocytes play a variety of complex nutritive and supportive roles in relation to neuronal metabolic homeostasis. For example, astrocytes take up glutamate and convert it to glutamine; removal of glutamate from the extracellular space protects surrounding cells from glutamate-induced excitotoxicity. Glutamate and glutamine are amino acids that are measured in ^{1}H-MRS when using short echo times. Alternatively, glutamate in the astrocyte can stimulate glycolysis with lactate production. Lactate is then released into the extracellular space and can also be taken up by neurons and used for energy generation.[88] In the immature brain, especially in the immature white matter, lactate is present in higher concentrations.[22,52]

Osmoregulation is another major metabolic task fulfilled by astroglia. Osmolytes synthesized by astrocytes or present in astroglia include taurine, hypotaurine, and myoinositol. Developmental changes in myoinositol have been described by Kreis and colleagues,[67,87] with a decrease of myoinositol during the first year of life and a marked reduction of myoinositol in the first weeks after birth regardless of the gestational age at birth. Studies indicate that astroglial cells are also able to synthesize creatine from glycine, which will need to be considered in interpreting creatine concentrations in brain[12,31] and its role as a neuroprotective agent.

Oligodendrocytes and Myelination

Oligodendrocytes, which produce myelin, can be divided into four cell types according to their stage of maturation: oligodendrocyte progenitor (NG2+), preoligodendrocyte (O4+, O1−), immature oligodendrocyte (O4+, O1+), and mature myelinating oligodendrocyte (O4+, O1+, MBP+, PLP+).

The progenitors originate from the proliferative subventricular zone and are bipolar and mitotically active. They are produced during the last months of gestation and in the early postnatal period. During migration in the white matter, differentiation into preoligodendrocytes occurs, which are multipolar cells retaining a proliferative capacity. This second cell type is the dominant one in the second half of gestation in the periventricular white matter. The immature oligodendrocyte is a multipolar cell that starts in the third trimester to ensheathe the axons in preparation for myelination. The last stage is differentiation into the mature, myelinating, highly multipolar cell. Each stage of differentiation can be marked by specific monoclonal antibodies (Fig. 40-19).[3]

Growth factors, hormones, and cytokines (basic fibroblast growth factor, neurotrophin-3, platelet-derived-growth factor, insulin-like growth factor type 1, interleukin-6, thyroid hormone) are implicated in oligodendrocyte maturation, but up to 50% of oligodendrocytes undergo programmed cell death (apoptosis) during development.[118] Preoligodendrocyte progenitors are highly vulnerable to oxidative stress, excitotoxic cascade (through α-3-amino-hydroxy-5-methyl-4-isoxazole propionic acid [AMPA]-kainate and NMDA receptors), and hypoxic-ischemic insults.[118]

^{1}H-MRS as an in vivo technique to assess metabolic composition of brain tissue can help in characterizing integrity of developing white matter. N-acetylaspartate (NAA), an amino acid specific to the CNS, has been shown to be uniquely localized in neuronal tissue of the adult brain, whereas during

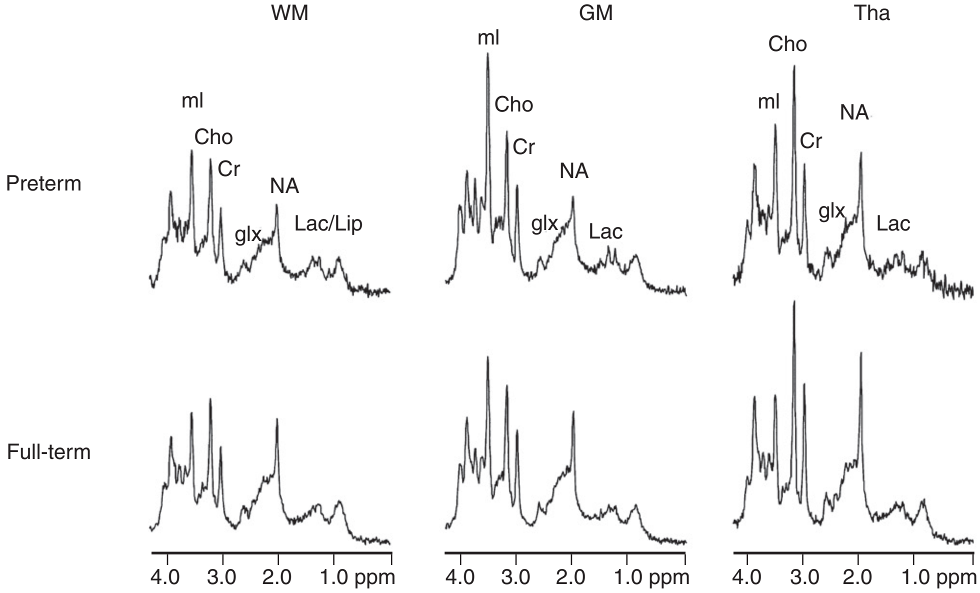

Figure 40–18. Averaged in vivo ^{1}H-MR spectra during human development in function of different regions of the brain: WM, white matter; GM, gray matter; Tha, thalamus. Metabolites identified are Lac, lactate; NA, N-acetyl-aspartate; glx, glutamine and glutamate; Cr, creatine and phosphocreatine; Cho, choline; mI, myoinositol. Spectra are scaled identically. Developmental changes in metabolite concentrations are illustrated by different peak heights comparing spectra from preterm and full-term newborns. *(Spectra analyzed by Roland Kreis, MR Center, Inselspital, University of Berne, Switzerland.)*

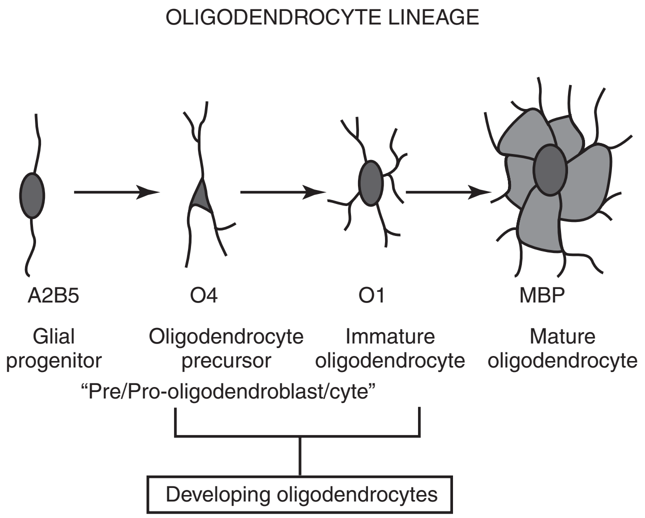

Figure 40–19. Schematic representation of the oligodendrocyte development showing their morphology and some major immunohistochemical markers (A2B5, 04, O1, and MBP [myelin basic protein]). (*Adapted from Back SA, et al: Immunocytochemical characterization of oligodendrocyte development in human cerebral white matter,* Soc Neurosci Abst *20:1722, 1996.*)

development it is also found in oligodendrocyte type 2 astrocyte progenitor cells and immature oligodendrocytes.[112] NAA has been shown to be an acetyl group source in the nervous system.[78] The major requirement for acetyl groups is lipid synthesis, which takes place immediately before myelin deposition in the developing brain. A marked increase of NAA shown in several studies (Hüppi and Lazeyras[53] for review) in the period from 32 to 40 weeks of gestation, just before the initiation of myelination, supports the importance of NAA in lipid synthesis (see Fig. 40-18). Regional differences in age-dependent changes of NAA concentrations during early brain development show stable concentrations in perithalamic voxels,[22] where myelination is already initiated at 32 weeks, and a marked increase in central cerebral white matter[68] between 32 and 40 weeks of gestation (see Fig. 40-18).

Myelination occurs over a protracted period, ending long after birth (Table 40-2). The chronology and rate of myelination vary with the brain structure. Structures that function first tend to be myelinated first. However, although myelination leads to a marked acceleration in nerve conduction, human and experimental studies have reported several examples of dissociation between the degree of myelination and the maturation of a given function. Myelination starts in the cerebral hemispheres around birth and is largely complete by the age of 2 to 3 years. There is no detectable myelination in the forebrain before the seventh gestational month, and this process continues in some parts until the years of maturity. Myelination is most intense in the telencephalon during the third trimester and postnatally.

TABLE 40–2 Sequence of Myelination Based on Histologic Analysis and Magnetic Resonance Imaging

Anatomic Region	MEDIAN AGE FOR DETECTION OF MYELIN: HISTOLOGY[124]	AGE FOR DETECTION OF MYELIN: MAGNETIC RESONANCE IMAGING[41]	
		T1-Weighted Images	T2-Weighted Images
Ventrolateral thalamus		28-30 wk	32 to 34 wk
Posterior limb of internal capsule	38/44 wk*	38-40 wk	Posterior portion 40-48 wk Anterior portion 56-70 wk
Anterior limb of internal capsule	50/87 wk	48-53 wk	70-90 wk

Central	50/119 wk	52-64 wk	90-106 wk
Peripheral	72/119 wk	70-90 wk	96-114 wk

*The first number corresponds to earliest identification of some myelin tubules by microscopic examination of hematoxylin and eosin stained sections. The second number corresponds to mature myelin stained with blue dye by eye observation.

Pathways of the olfactory, optic, acoustic, and sensorimotor cortex are the first to be myelinated, whereas projection and association pathways are the last. Projection fibers begin myelination before association fibers. The myelination of association fibers lasts until adulthood.

Imaging Characteristics of Myelination

On histologic examination, mature myelin is present at 37 to 40 postconceptional weeks in the posterior limb of the internal capsule and in the lateral cerebellar white matter (see Table 40-2). Myelination advances at differing rates in different regions of the brain. Myelination occurs in an orderly and predictable fashion, proceeding cephalad from the brainstem at 29 weeks to reach the centrum semiovale by 42 weeks. Myelination advances at differing rates in different regions of the brain and is visible at different times on T1-weighted (lipid: high signal) and T2-weighted (water: high signal) MRI, the classic imaging sequences on conventional MRI.[5,8] The exact reasons for these differences are not clear. However, it is known that the T1 shortening correlates temporally with the increase in cholesterol and glycolipids that accompany the formation of myelin from oligodendrocytes.[90] Furthermore, the T2 shortening correlates temporally with the tightening of the spiral of myelin around the axon, the conformational changes in the myelin proteins, and saturation of polyunsaturated fatty acids in the myelin membranes. Portions of the proteins, cholesterol, and glycolipids that compose myelin are hydrophilic and form hydrogen bonds more strongly with water molecules. With an increase in bound water to the myelin building blocks, there is a consequent decrease in free water and an increase in T1 shortening times. This reduction in free water accompanying the preparation for myelination may explain the pattern of T1-weighted MRI changes preceding anatomic myelination by histologic analysis (see Table 40-2). Sensory pathways are the first to myelinate: vestibular, acoustic, tactile, and proprioceptive senses are myelinated at term birth. A shortened T2 relaxation time and therefore a T2 hypointense signal is observed in the ventroposterolateral nuclei of the thalamus as early as 28 weeks' gestation, in the posterior limb of the internal capsule as early as 36 weeks' gestation, and in the corona radiatae and the sensorimotor cortex at term. The signal alteration in the sensory motor cortex might also be due to a more advanced organization of cortical neurons, oligodendroglial cells, synaptic density, and dendrite formation, which would cause decreased interstitial water and a shortening of the T2 relaxation time (Fig. 40-20).[65] Phylogenetically older structures such as the inferior and superior cerebellar pedunculi and vermis are myelinated before term, whereas the cerebellar hemispheres are myelinated much later.[110] Similarly, the amygdala and hippocampus are partly myelinated at term.

Changes in the volume of myelinated white matter have also been determined by volumetric MRI studies, with myelin comprising less than 5% of total brain volume at 34 weeks' gestation and showing a rapid increase thereafter.[55] The dramatic fivefold increase in myelinated white matter after 34 weeks is of major interest for the understanding of brain injury during this period. This increase in myelin is presumed to be the result of the maturation of oligodendrocytes that have been actively differentiating during the immediately preceding period.

Microglia and Brain Macrophages

Microglia constitutes 5% to 15% of the total cerebral cellular population. The prevailing view is that microglial cells are derived from circulating precursor in the blood that originates from bone marrow.[72] During the first trimester of human gestation, penetrating cells have an ameboid morphology, with large ovoid cell bodies and no or few short processes, and express macrophage antigenic characteristics depending on their location and activation state. This macrophage-like morphology evolves into an intermediate and a mature phenotype with a smaller cell body and longer processes. At midgestation, macrophage-microglia populations are mostly detected in white matter pathways,

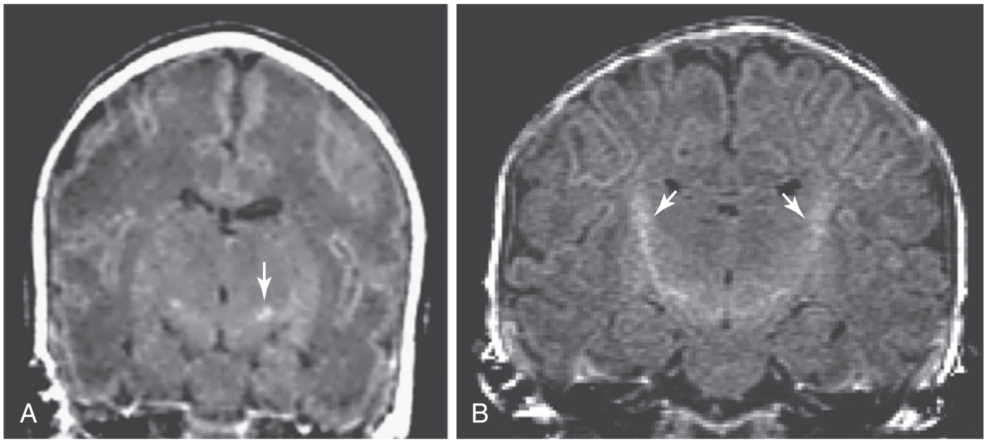

Figure 40–20. T1-weighted MR images illustrating progress of myelination. **A**, A 28 weeks' gestation distinct T1 shortening (high signal) is seen only in a small perithalamic region *(arrow)*. **B**, At 40 weeks, distinct T1 shortening (high signal) is seen throughout the internal capsule reaching the central cortex *(arrows)*.

such as the external and internal capsules and corpus callosum. As suggested from rodent studies, these cells could contribute to physiologic developmental remodeling through phagocytosis of cellular fragments produced by neurodevelopmental apoptosis and elimination of exuberant axons and dendrites.[74] However, the correlation between regressive events and the distribution of macrophages is not clear, suggesting other possible functions for these cells during development.

In the case of a cerebral lesion, experimental data support a neurotoxic role for the cerebral macrophage through the production of free radicals and nitric oxide. Under pathologic conditions, microglial cells can be transformed into functional brain macrophages with the reappearance of specific cell surface markers.

After development, mature microglia constitute a quiescent cellular population with small cell bodies, numerous long, thin processes, and a possible role in the regulation of the extracellular environment and immune protection of the brain.

Brain Vascular Development

Despite its major role in brain development and functioning, the ontogeny of the brain vasculature has not been the focus of numerous studies. Precise description of the successive steps of brain vessel development and its chronology is still lacking, and little information is available on the molecular mechanisms controlling the development and patterning of brain vessels. Accordingly, the exact timing of the switch from a neuronal anaerobic metabolism to an aerobic one is unknown, although this information might be critically important in understanding the potential consequences of hypoxia or ischemia at successive stages of brain development.

As soon as the neural tube is formed, blood vessels penetrate the primitive neuroepithelium. During migration of neocortical neurons, the density of blood vessels is rather low, with significant distances separating migrating cells from blood vessels. Penetration of vessels in the cerebral mantle is radial and ventriculopetal, starting from the leptomeningeal plexus and directed toward the ventricle.[69,84] No transventricular, paraventricular, or recurrent arteries ending in deep white matter have been identified. Horizontal collaterals progressively appear with a ventriculofugal gradient that reaches white matter at approximately 20 gestational weeks in the human fetus. The chronology of the horizontal ramification of vessels starts at approximately 20 weeks of gestation in the subplate and deep cortical layers, reaches layer III approximately at birth, and is completed (layers II and I) in the postnatal period.

Most neopallial vessels remain devoid of apparent muscularis until the final weeks of gestation.[70] Muscularis development follows a ventriculopetal gradient. The lack of muscular layers around neopallial arteries and the gradient of muscularization of these vessels could explain the high susceptibility of immature arteries to deep white matter and germinal matrix hemorrhages and the lack of vasomotor autoregulation in periventricular areas during a large part of the second half of gestation or the corresponding period in the preterm infant.

ABNORMAL BRAIN DEVELOPMENT AND DISORDERS

As a rule, the different categories of congenital malformations of the CNS reflect the time at which a noxious event disrupted the normal sequence of CNS development rather than the nature of the noxious event itself. Therefore in this section the congenital CNS disorders are arranged according to time of onset of the morphologic alteration. (See also Parts 7 and 8 of this chapter.)

Disorders of Neural Tube Formation and Prosencephalic Development

CRANIORACHISCHISIS TOTALIS, ANENCEPHALY, MYELOSCHISIS, ENCEPHALOCELE, MYELOMENINGOCELE, AND OCCULT DYSRAPHIC STATES

Craniorachischisis totalis is secondary to total failure of neurulation with the formation of a neural platelike structure without overlying tissue. The onset of this malformation is no later than 20 to 22 days of gestation and most cases are aborted spontaneously during embryonic life.

Anencephaly results from failure of anterior neural tube closure and occurs before 24 days of gestation. It is often associated with polyhydramnios. Approximately three fourths of these infants are stillborn, and the remainder die in the neonatal period.

Myeloschisis results from failure of posterior neural tube closure and occurs before 24 days of gestation. A neural platelike structure without overlying tissue replaces large parts of the spinal cord. Most of these infants are stillborn.

Encephalocele is usually considered to be a restricted disorder of anterior neural tube closure, although its precise mechanisms remain unknown. It occurs before 26 days of gestation. Encephalocele is occipital in three fourths of cases, sometimes frontal (where it may protrude into the nasal cavities), and rarely temporal or parietal. Neural tissue (most often from the occipital lobe) in the encephalocele usually displays a normal gyration and underlying white matter and is connected to the brain through a narrow neck (Fig. 40-21). Hydrocephalus is present in approximately half of the cases. In cases in which the encephalocele is located in the lower occipital region or upper cervical area, cerebellum is usually present in the encephalocele, occipital tissue is present in approximately half of the cases, and Chiari II malformation is associated (producing Chiari III malformation). Corpus callosum agenesis and anomalies of venous drainage are frequently associated. Encephaloceles are observed in a variety of chromosomal disorders (e.g., trisomies 13 and 18) and syndromes (e.g., Walker-Warburg, Meckel-Gruber, Dandy-Walker, Joubert, Goldenhar-Gorlin, Knobloch, and Robert syndromes).

Myelomeningocele is a restricted disorder of posterior neural tube closure that occurs before 26 days of gestation. (See also Chapters 8 and 11 for in utero diagnosis and treatment.) It involves all layers, including spinal cord, nerve roots, meninges, vertebral bodies, and skin. Approximately three fourths of myelomeningoceles have a lumbar localization

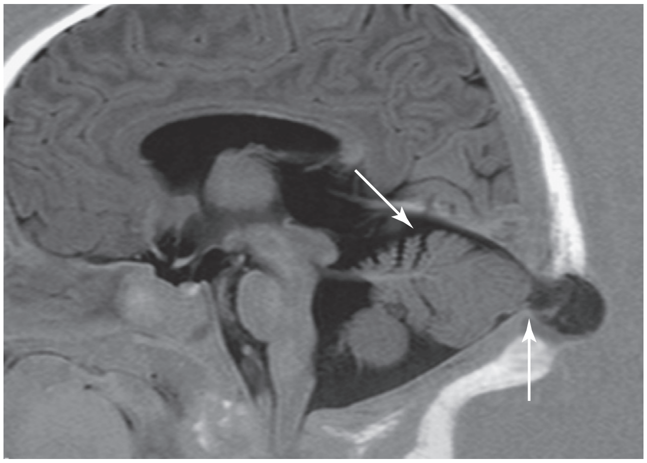

Figure 40–21. Occipital encephalocele *(right arrow)* with moderate displacement of the cerebellum *(left arrow)* and dilation of ventricular system, particularly the fourth ventricle. *(Image courtesy of J. Delavelle, Department of Radiology, University Hospitals of Geneva, Geneva, Switzerland.)*

(thoracolumbar, lumbar, or lumbosacral). Hydrocephalus is present in 70% of cases, especially when the lumbar region is involved. Chiari II malformation is almost always present in lumbar myelomeningoceles (Fig. 40-22). Location and extent of the lesion determine the clinical symptoms. Thoracic myelomeningoceles have a generally poor prognosis. Varying degrees of paresis (often severe) of the legs and sphincter dysfunction are the major clinical signs. Although myelomeningocele can be observed in chromosomal abnormalities and in single-gene disorders, the vast majority of isolated nonsyndromal cases are thought to be due to an interaction of genetic susceptibility (e.g., specific mutations in the methylenetetrahydrofolate reductase gene) with environmental factors (such as valproate exposure or maternal type 1 diabetes mellitus).

A newborn with a meningomyelocele presents the clinician with difficult decisions about what to tell the parents and whether to close the spinal defect surgically. Surgery should be undertaken within the first 24 hours after birth to prevent further deterioration of the spinal cord and nerve roots and to prevent infection (meningitis). Fetal and neonatal therapy of meningomyelocele is discussed in Chapter 11 and Part 8 of this chapter.

Factors that influence the decision for surgical closure include size and location of the lesion, the technical feasibility of closure, the prognosis for ambulation, the presence or absence of associated abnormalities (hydrocephalus, kyphosis, or other major structural abnormalities), the availability of personnel and a facility to provide adequate care for the infant, and the infant's family structure and the attitudes of the family toward the defect and its consequences. The usual decision is to proceed with early surgical closure of the spinal defect, followed by placement of a ventriculoperitoneal shunt if hydrocephalus is present (see Part 8 of this chapter). Thereafter, the infant requires long-term neurosurgical, orthopedic, and urologic follow-up to maintain shunt stability, promote ambulation if possible, and minimize the untoward effects of multiple urinary tract infections.

Occult spinal dysraphisms are considered to be disorders of caudal neural tube formation (secondary neurulation) and include distortion of the spinal cord or roots by fibrous

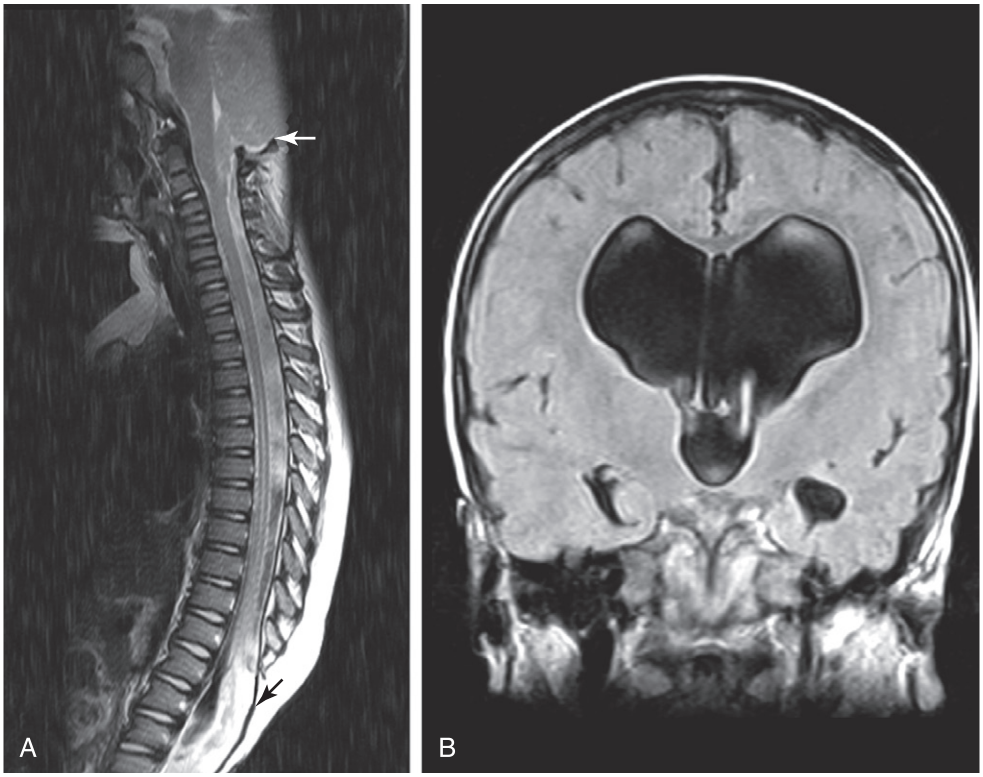

Figure 40–22. A, Lumbar myelomeningocele *(black arrow)* with distal displacement of medulla and cerebellum *(white arrow)* (Chiari malformation) with associated hydrocephalus (B). *(Image courtesy of J. Delavelle, Department of Radiology, University Hospitals of Geneva, Geneva, Switzerland.)*

bands and adhesions, intraspinal lipomas, epidermoid cysts, fibrolipomas, subcutaneous lipomas, tethered cord (the most common condition), and diastematomyelia. Clinical symptoms are variable (absent, minimal, moderate, or severe) according to the degree of neural tissue involvement. Clinical signs include motor and sensory deficits in the lower and sometimes upper (when posterior fossa or cervical cord malformations are associated) limbs, bowel and bladder dysfunction, and ophthalmologic complications (when hydrocephalus is present).

HOLOPROSENCEPHALY AND AGENESIS OF THE CORPUS CALLOSUM

(See also Part 7 of this chapter.)

Holoprosencephaly refers to a large spectrum of brain malformations sharing a common embryologic origin. The frequency of holoprosencephaly is approximately 1 per 10,000 births, including miscarriages and terminations beyond 20 weeks of gestation, although it reaches approximately 40 per 10,000 if embryos are included, suggesting that holoprosencephaly is often accompanied by early embryonic loss.

Holoprosencephaly results from a defect in the cleavage of the prosencephalon in the rostrocaudal axis (between the diencephalon and the telencephalon) and in the transversal axis (division into two hemispheres). Holoprosencephaly can be divided into alobar variants (absence of interhemispheric fissure, corpus callosum, and third ventricle; unique ventricle; fusion of thalami), semilobar variants (presence of the interhemispheric fissure in the caudal part), and lobar (presence of a third ventricle; frontal horns partially formed; presence of the corpus callosum; hypoplastic frontal lobes) according to the severity of the malformation (Fig. 40-23). There seems to be a continuum between lobar holoprosencephaly and septo-optic dysplasia (Fig. 40-24). In all forms of holoprosencephaly, the septum pellucidum and the trigone are missing, whereas the olfactory bulbs and tracts are usually hypoplastic or absent (arhinencephalia).

The most severe forms of dysmorphic facies are usually found in alobar holoprosencephalies, but this is not a general rule and facial anomalies do not always reflect the severity of the brain malformations. Malformations affecting mainly cardiac, skeletal, genitourinary, and gastrointestinal organs are frequent. In the most severe cases, neurologic signs are already present in the neonatal period and include apneas, seizures, tonic spasms, lack of neurologic development, and death.

Causes of holoprosencephaly are variable, with genetic, chromosomal, syndromic, and environmental etiologies (see Box 40-2). Most cases are sporadic, although some familial cases have been reported. Several maternal factors have been associated with holoprosencephaly, such as maternal diabetes or ethanol consumption. Holoprosencephaly is also observed in several syndromes, including the Smith-Lemli-Opitz syndrome characterized by abnormalities in cholesterol metabolism.

Approximately 12 loci, located on 11 chromosomes, have been identified for holoprosencephaly (HPE1 through HPE12). Genes *SIX3* (coding for a homeoprotein), *SHH* (transduction factor; see earlier), *ZIC2* (zinc finger transcription factor), and *TGIF* (TG-interacting factor, interacting with Smad2) have been identified as corresponding to loci HPE2, HPE3, HPE5, and HPE4, respectively. Among these genes, *SHH* is considered to be the most important one. Interestingly, abnormalities affecting genes located downstream to *SHH* in the *SHH* pathway also induce holoprosencephaly.

Agenesis of the corpus callosum is a relatively frequent malformation. Its prevalence in the general population is unknown because it might occur in a totally asymptomatic manner. Its prevalence in a population with mental retardation reaches 2% to 3%. Agenesis of the corpus callosum represents approximately 50% of the malformations of the midline.

Agenesis of the corpus callosum can be partial (affecting in most cases the posterior portion, except when it is associated with holoprosencephaly) or complete. The lateral ventricles are deformed by the fibers of the cerebral hemispheres that were destined to form the corpus callosum and that form the Probst bundles running longitudinally along the lateral ventricles. The Probst bundles are inconsistently present, and their presence has been considered a sign of better prognosis.

Corpus callosum agenesis can be associated with other brain malformations (such as neuronal migration disorders) or with extracerebral malformations. In the presence of associated malformations, the prognosis of agenesis of the corpus callosum is considered poor in most cases. In contrast, the prognosis of isolated agenesis of the corpus callosum (partial or complete) is much more variable, with some

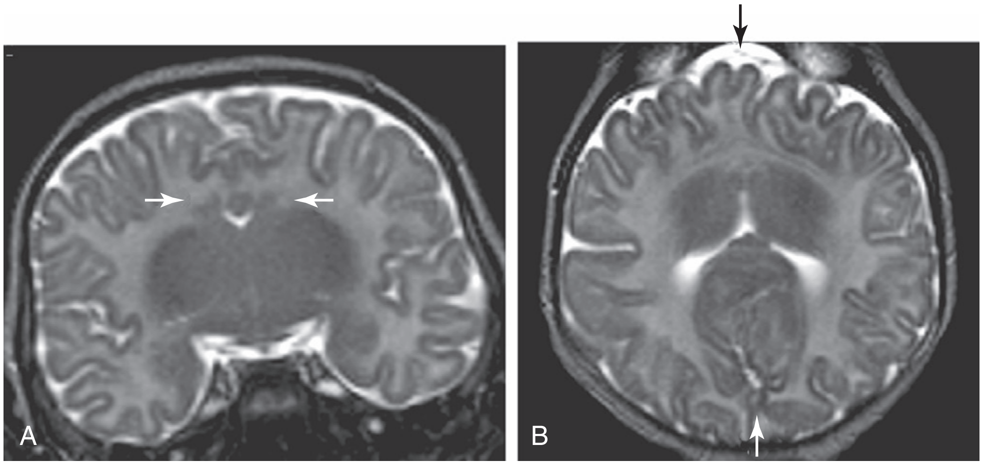

Figure 40–23. Semilobar holoprosencephaly (**A**) with absence of corpus callosum, anterior interhemispheric fissure (*black arrow* in **B**), and frontal horns of lateral ventricle (*white arrows*), but with presence of interhemispheric fissure (*white arrow*) in the posterior caudal part (**B**). cases having a totally normal or near-normal neurologic outcome, some cases with moderate or severe neurologic handicap, and some cases evolving toward death within the first days or months after birth. Because of the relatively low number of reported cases and the relatively short follow-up in many of these cases, providing reliable figures for the neurologic outcome of the isolated malformation remains difficult.

DANDY-WALKER MALFORMATION

Although it does not primarily affect the cerebral hemispheres, we include the Dandy-Walker malformation in this chapter because it is frequently associated with malformations of the cerebral hemispheres (important for differential diagnosis and for determination of the outcome), it often has neonatal signs, and it is the prototype of cerebellar malformations observed in the neonatal period.

Dandy-Walker malformation results from abnormal development of the rhombencephalon, probably occurring between the 7th and the 10th gestational weeks. Dandy-Walker malformation is observed in approximately 1 per 25,000 to 30,000 births. This malformation is usually sporadic, with a few reported familial cases. Its etiology is unknown, and environmental factors (e.g., ethanol, warfarin sodium, viral infection) have been reported in a few cases.

Dandy-Walker malformation classically consists of three major abnormalities: (1) enlargement of the posterior fossa and elevation of the tentorium, (2) cystic dilation of the fourth ventricle, and (3) partial or complete agenesis of the corpus callosum. Hydrocephalus is often present but may appear late during pregnancy or even after birth. Other brain malformations (in particular, abnormalities of the midline and neuronal migration disorders) are observed in up to 70% of cases (Fig. 40-25). Extraneurologic malformations involving the heart, kidneys, limbs, and face are also frequent. The associated neurologic and extraneurologic abnormalities have a major impact on the prognosis of the Dandy-Walker malformation, with better prognosis often (but not always) associated with cases of isolated Dandy-Walker malformation.

As reviewed by Volpe,[119] a prominent posterior fossa cerebrospinal fluid collection can be divided into three categories: (1) enlargement of the fourth ventricle (including Dandy-Walker malformation, other disorders with agenesis of the cerebellar vermis such as Joubert syndrome and other familial vermian ageneses, and trapped fourth ventricle); (2) enlarged cisterna magna; and (3) arachnoid cyst.

Abnormalities of Neuronal Proliferation

MICROCEPHALY

(See also Part 7 of this chapter.)

Microcephaly is defined by an occipitofrontal circumference below −2 standard deviations (SD) for age and sex. Severe microcephaly refers to a circumference below −3 SD. Skull growth is determined by brain expansion, which takes place during the normal growth of the brain during pregnancy and infancy. Microcephaly most often occurs because of failure of the brain to grow at a normal rate. Any condition that affects brain growth can cause microcephaly. Primary microcephaly is distinguished from secondarily acquired microcephaly, in which the brain attains the expected size during pregnancy

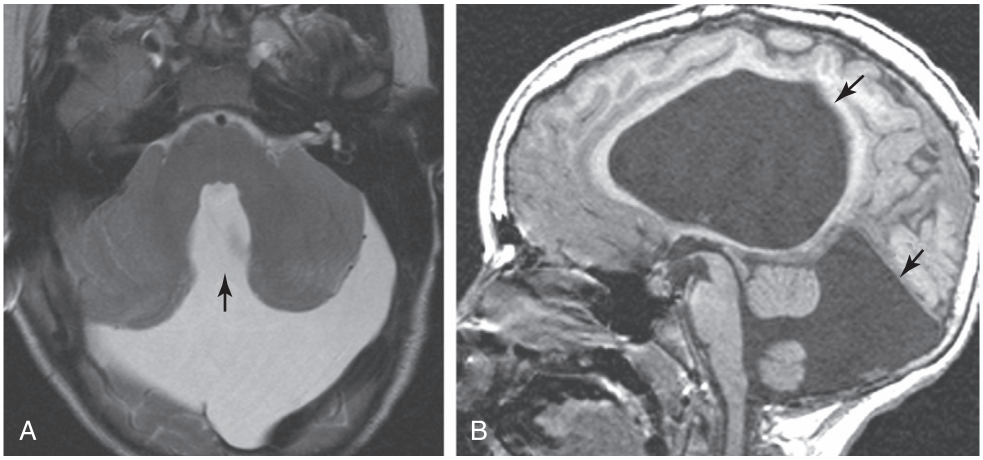

Figure 40–25. Dandy-Walker malformation with enlargement of posterior fossa. **A**, Axial T2-weighted MRI with absence of cerebellar vermis *(arrow)*. **B**, Sagittal T1-weighted MRI with elevation of the tentorium *(bottom arrow)* and hydrocephalus *(top arrow)*. *(Image courtesy of J. Delavelle, Department of Radiology, University Hospitals of Geneva, Geneva, Switzerland.)*

but subsequently fails to grow normally. Microcephaly can be divided into acquired etiologies (e.g., anoxic/ischemic brain damage, severe malnutrition, fetal alcohol syndrome, intrauterine infection, maternal hyper-phenylalaninemia and phenylketonuria, anticonvulsant drugs, irradiation) and primary developmental microcephaly (see Box 40-3). The latter can be divided into (1) isolated microcephaly (primary microcephaly); (2) microcephaly associated with other brain malformations; (3) microcephaly associated with chromosome disorders; (4) microcephaly as part of a syndrome with multiple congenital anomalies (e.g., Neu-Laxova, Seckel, Rubinstein-Taybi, and Cornelia de Lange syndromes, microcephalic osteodysplastic dwarfism); and (5) microcephaly associated with biochemical disorders.

Primary Genetic Congenital Microcephaly

A standard classification of malformations of abnormal cortical development[6] divides lesions into those due to neuronal and glial proliferation in the germinal zones versus those due to cellular migration. Abnormal neuronal and glial proliferation leads to micrencephaly vera, microcephaly with simplified gyral pattern and, when combined with migration defect (see later), microlissencephaly.[121] The head circumference is very small in all those disorders, often in the range of 24 to 28 cm at birth. Brain weights have been among the smallest ever reported (below 100 gm). Precise classification of this group remains fluctuant and consensus has not been reached. The incidence of congenital microcephaly below –2 SD is approximately 3 to 4 per 100 births. Congenital microcephaly below –3 SD occurs in approximately 1 to 2 per 1000 births.

Micrencephaly Vera

Micrencephaly vera (or true micrencephaly or radial microbrain) (Fig. 40-26) is a genetic condition in which the brain is abnormally small because of a reduced number of neurons, but in which a normal or subnormal gyral pattern is present and no other gross pathologic abnormality is present. Brain weight is typically less than 500 g (one third of normal values and comparable with that of early hominids). Mental retardation is usually moderate. Eight different loci have been mapped, and 5 genes are currently cloned: *MCPH1* (microcephalin), *CDK5RAP2* (MCPH3), *ASPM* (MCPH5), *CENPJ* (MCPH6), and deoxynucleotide carrier (DNC). Inheritance is autosomal recessive or X-linked recessive (XLR) for one locus.

The *MCPH1* locus located in 8p22-pter encodes microcephalin, which could play a role in the initiation of chromosome condensation during mitosis, in DNA repair following ionizing radiation damage, or in cell cycle timing in neural progenitors. Microcephalin is mainly expressed in brain, liver, and kidney. In mouse, it is expressed in fetal brain during neurogenesis (forebrain, germinative area) and, in human cells, it is localized at the centrosome level. The gene is poorly conserved in vertebrates: 57% sequence identity between mouse and human orthologs (mean human-mouse protein sequence identity: 85%). So far, mutation has been exclusively reported in inbred Pakistani families.[40]

The MCPH3 locus located in 9q33.3 encodes the cyclin-dependent kinase 5 regulatory associated protein 2 gene (*CDK5RAP2*). Nonsense mutations were identified as a cause for MCPH3 in two Northern Pakistani families.[13,15] CDK5 is a protein kinase, active in the central nervous system, with numerous neuron-specific roles in processes including neurogenesis, neuronal migration, and neurodegeneration. *CDK5RAP2* is an inhibitor of CDKR1 and thus also an inhibitor of CDK5. Human *CDK5RAP2* shows centrosomal localization in HeLa cells at various stages of mitosis.[15,17,24,85] In murine embryos at E15.5, CDK5RAP2 was widely distributed, but was most prominent in the brain and the spinal cord.[13,117] In *Drosophila*, the *CDK5RAP2*-homolog centrosomin (cnn) is required to recruit various proteins to the centrosome.[18,113] In cnn mutant embryos, centrosomes fail to function during mitosis as major microtubule organizing centers, leading to dramatic mitotic defects in embryos.

The MCPH5 locus in 1q31 corresponds to the *ASPM* gene, a human ortholog of the *Drosophila* melanogaster "abnormal spindle" gene (asp), identified by homozygosity mapping and found responsible for approximately one half of the micrencephaly vera (MV) cases in all ethnic backgrounds. The gene contains multiple repeats of 20-amino-acid sequence beginning with isoleucine (I) and glutamine (Q), called *IQ repeat*. All published mutations lead to loss of function.[17] In *Drosophila*, asp is essential for normal mitotic spindle function in embryonic neuroblasts.[120] The protein encoded shows consistent increase in size through evolution. The predominant difference between Asp and ASPM is a single large insertion coding for « IQ domains ». The number of IQ domains seems related to CNS complexity: roundworm: 2 IQ; *Drosophila*: 24 IQ; mouse: 61; human: 72-80.

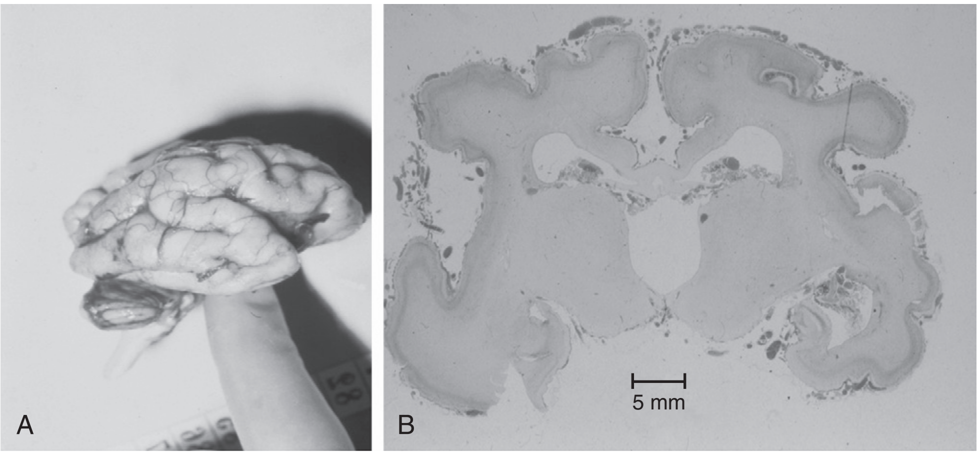

Figure 40–26. Radial microbrain. **A**, Gross specimen. **B**, Microscopic section. (*From Barkovich AJ, et al. Formation, maturation, and disorders of brain neocortex,* AJNR Am J Neuroradiol *13:423, 1992, with permission.)*

The MCPH6 locus in 13q22.2 encodes the centrosome associated protein J (CENPJ, also known as CPAP for centrosome protein 4.1 associated protein). CENPJ is located in the centrosome through the cell cycle and interacts with the non-erythrocyte 4.1 protein 135 variant (4.1R-135). The E1235V mutation found in an affected patient occurs in a Tcp10 domain of CENPJ, which interacts with 4.1R-135. During cell division, this protein plays a structural role in the maintenance of centrosome integrity and normal spindle morphology, and it is involved in microtubule disassembly at the centrosome.[7] CENPJ is widely distributed in the developing embryo. It is expressed at E15 in the neuroepithelium lining the lateral ventricles of the mouse forebrain and has a higher expression in the newly forming layers of the cortical plate. CENPJ may have a role in the control of centrosome microtubule production during neurogenic mitosis.[16]

The DNC-SLC25A19 gene (17q25) is responsible for the Amish type of micrencephaly vera (MV), a unique autosomal recessive disorder observed in Amish, characterized by extreme microcephaly (−6 to −12 SD), death within the first year, and associated with alpha-ketoglutarate aciduria. SLC25A19 encodes for a nuclear mitochondrial DNC.[100] The gene is composed of 9 exons coding for a protein of 16,5 kb. Slc25a19 knockout mice do not survive after E12. Affected embryos at E10 have neural tube closure defect and increased alpha-ketoglutarate in the amniotic fluid.

Other loci have been mapped for micrencephal vera/microcephaly with simplified gyral pattern (MV/MSG). These include MCPH2 (19q13.1-q13.2),[99] MCPH4 (15q15-q21),[59] and MRXS9 (Xq12-q21.31). About 20% of families are still unlinked.

Microcephaly with Simplified Gyral Pattern

Microcephaly with simplified gyral pattern are disorders defined by congenital severe microcephaly, reduced number and shallow appearance of gyri, and normal to thin cortex. Two clinical variants are delineated, one with a normal or thin corpus callosum and one with agenesis of the corpus callosum. Inheritance is autosomal recessive. Micrencephaly vera and microcephaly with simplified gyral pattern are likely part of a continuous phenotype, with mild microcephaly with simplified gyral pattern being seen in some patients from families with typical micrencephaly vera.[98]

Beyond the three genes described previously, several other loci have been mapped for micrencephaly vera or microcephaly with simplified gyral pattern. Approximately 20% of families are still unlinked.

MICROLISSENCEPHALY

The microlissencephaly disorders have simplified gyri but are distinguished from microcephaly with simplified gyral pattern by a cortex that is thicker than in normal brains. At least four different types have been identified on imaging and clinical grounds: microlissencephaly with thick cortex (MLIS1, or Norman-Roberts syndrome), microlissencephaly with thick cortex, severe brainstem, and cerebellar hypoplasia (MLIS2, or Barth syndrome), microlissencephaly with intermediate cortex and abrupt anteroposterior gradient, and microlissencephaly with mildly to moderately thick (6 to 8 mm) cortex. Inheritance is autosomal recessive. No gene has been mapped.

MEGALENCEPHALY

(See also Part 7 of this chapter.)

Megalencephaly (or macrocephaly) corresponds to an excess increase of the brain volume. It can affect one (hemimegalencephaly) or both hemispheres (symmetric megalencephaly).

Symmetric megalencephaly can be associated with other brain malformations, including hydrocephaly, tumors, or gyration abnormalities (e.g., pachygyria). Some cases of symmetric megalencephaly have a familial transmission with different modes of inheritance. Some of these transmissible forms are accompanied by familial mental retardation. Megalencephaly can also be part of a syndrome, such as Weaver and Proteus syndromes. In the absence of associated malformation or familial history, the prognosis of isolated symmetric megalencephaly is difficult to determine because some cases have a normal evolution, whereas mental retardation can be observed in other cases. Symmetric megalencephaly must be differentiated from congenital macrocrany with normal brain volume but increased pericerebral spaces. This entity, sometimes called external hydrocephaly, can have a familial transmission (usually autosomal dominant) and often has an excellent neurologic prognosis.

Hemimegalencephaly is characterized by increased growth of one hemisphere or a part of it. This hemisphere is abnormal, with foci of pachygyria, polymicrogyria, heterotopias, and white matter gliosis. Brainstem and cerebellum can also be affected. Hemimegalencephaly can be isolated or associated with hemihypertrophy (as part of a syndrome such as Protée syndrome, Klippel-Trenaunay-Weber syndrome, or Ito hypomelanosis) or, in some cases, with other malformations as part of Bourneville sclerosis. Hemimegalencephaly is usually sporadic. Its pathophysiologic process remains unclear but could involve genes implicated in brain symmetry such as LEFTY1, LEFTY2, or ZIC3. Patients with hemimegalencephaly usually display a macrocrania, hemiplegia, severe or intractable epilepsy, and developmental delay that can be severe and exacerbated by the epilepsy.

Disorders of Neuronal Migration

Abnormalities of neuronal migration have been described in a large variety of syndromic, genetic, and environmental conditions (see Box 40-4).

CLASSIC LISSENCEPHALIES (TYPE I LISSENCEPHALIES)

Classic lissencephalies form a genetically heterogenous group with highly variable neuroradiologic signs. Complete agyria (lack of gyration) has to be distinguished from pachygyria (incomplete gyration with a reduced number of flat and broad gyri separated by shallow sulci).[4] The shallow sylvian fissures result in a figure-eight appearance of the axial brain sections. Aspect and severity can vary according to the cortical area and generally follow a rostrocaudal gradient. Hippocampus and temporal cortex are often less affected. Dobyns and Truwit have proposed a radiologic score of severity based on the presence and location of agyria, pachygyria, and subcortical band heterotopias.[30] On MRI, the cortex appears thickened: 5 to 20 mm, whereas the normal thickness is between 2.5 and 4 mm. The microscopic cytoarchitecture is abnormal (reduction of the number of cortical layers and abnormal neuronal densities), yielding a neuropathologic pattern that is specific for each molecular abnormality described thus far. Lateral ventricles can be enlarged in their posterior portion (colpocephaly). Lissencephaly variants are characterized by major abnormalities of the corpus callosum and of the cerebellum. By definition, head circumference is greater than −3 SD in classic lissencephalies and is less than −3 SD in microlissencephalies (see earlier). The incidence of classic lissencephaly is estimated to be 1.2 cases per 100,000 live births.

LIS1 Mutations (Isolated Lissencephaly and Miller-Dieker Syndrome)

Abnormalities of the *LIS1* gene (platelet-activating factor acetylhydrolase isoform 1B alpha subunit gene, PAFAH1B1), which encodes the *LIS1* (PAFAH1B1) protein, account for the pathology seen in 40% of patients with lissencephaly. Deletions and nonsense mutations of *LIS1* induce an agyri-pachygyric phenotype with a posterior-anterior gradient (posterior being more severe; grade 2-3, according to Dobyns and Truwit[30]). Missense mutations can induce less severe phenotypes (grade 4, according to Dobyns and Truwit[30]). The cortex is thickened (10 to 20 mm), disorganized, and generally composed of four layers: a large molecular layer, a layer of superficial neurons, a paucicellular layer containing myelinated fibers, and a deep layer containing neurons that failed to reach their final target. The 17p13 deletion, which contains the *LIS1* gene, is responsible for the Miller-Dieker syndrome, which combines a grade 1 lissencephaly and dysmorphic features (prominent forehead, bitemporal hollowing, micrognathia, malpositioned and/or malformed ears, short nose with upturned nares and low nasal bridge, long and thin upper lip, and late tooth eruption) (Fig. 40-27). Septum calcifications are sometimes observed.

DCX Mutations

The *DCX* or *XLIS* gene, encoding doublecortin or DCX and located on the X chromosome, is responsible for the disease in about 40% of patients with lissencephaly and in 85% of patients with subcortical laminar heterotopia.[29,42,89] In boys, mutations induce a classic lissencephaly (grade 1 to grade 4) with a thickened cortex (10 to 20 mm) and a rostrocaudal gradient (i.e., a gradient reverse to that observed in patients with *LIS1* mutations). Heterozygous girls display a subcortical laminar heterotopia, which consists of a gray matter layer of variable thickness located between the normally located superficial cortical gray matter and the lateral ventricle ("double cortex"). This double cortex can be limited to the anterior part of the hemispheres. The clinical phenotype in females is variable and ranges from a complete lack of neurologic signs to mental retardation and epilepsy. Female carriers do not have a preferential X chromosome inactivation and, therefore, a normal MRI finding does not exclude the presence of a carrier status. Results of neuropathologic studies have shown that brains from patients with *LIS1* mutations exhibited the classic inverted four-layer lissencephalic architecture and unique cytoarchitectural findings, including a roughly ordered 6-layer lamination in male patients with *DCX* mutations and lissencephaly.

TUBA3 Mutations

Alpha 3 tubulin gene *TUBA3* mutations have been described recently[63] in one male patient and in one female patient. The first patient presented with a classic lissencephaly with a thick disorganized cortex and, clinically, with severe epilepsy, mental retardation, and motor deficits. The second patient exhibited less severe cortical abnormalities with temporal and rolandic pachygyria and abnormal organization of the hippocampus. Both patients had corpus callosum agenesis, inferior vermis abnormalities, and brainstem hypoplasia. The *TUBA3* gene is the human homolog of the murine *Tuba1*, which is expressed during early embryonic development. *Tuba1* mutations impair the ability of the protein to bind GTP (guanosine triphosphate) and to form native heterodimers with β-tubulin, which is very important for microtubule function. Mutation in murine *Tuba1* induces abnormal neuronal migration with disturbances in layers II/III and IV of the visual, auditory, and somatosensory cortices.

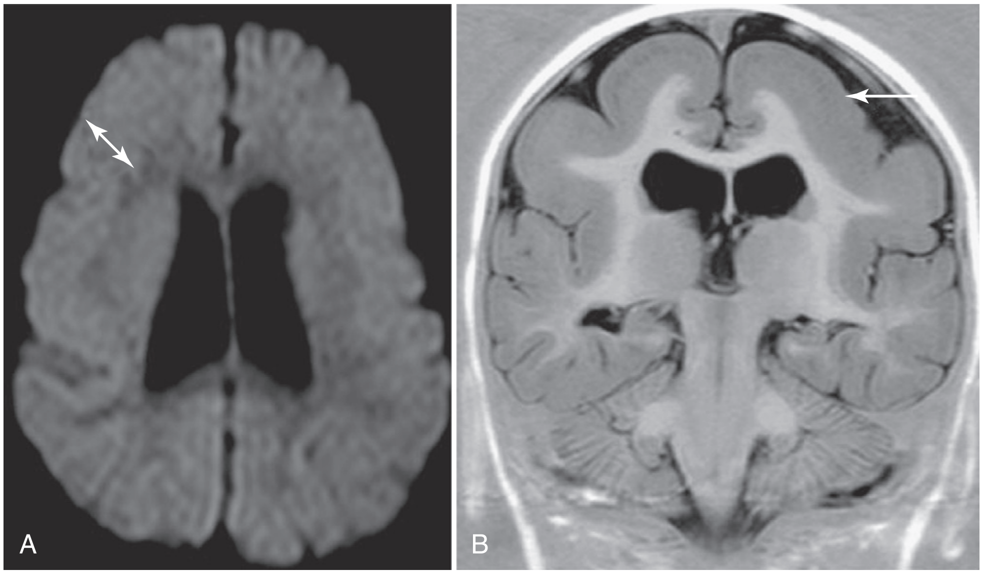

Figure 40–27. Type 1 lissencephaly, or Miller-Dieker syndrome, with (**A**) pachygyric "four-layered" thickened cortex (*arrow*). **B**, Axial diffusion weighted image also characterizes thickened cortex compared with underlying white matter (*arrow*). (*Image courtesy of J. Delavelle, Department of Radiology, University Hospitals of Geneva, Geneva, Switzerland.*)

ARX Mutations

ARX (Aristales-related homeobox) gene mutations cause a particular classic X-linked lissencephaly with or without corpus callosum agenesis. The cortex in three layers of *ARX* lissencephalies is less thick (5 to 10 mm) than in the other classic lissencephalies and the cortical abnormality displays a rostrocaudal gradient (frontal regions being more affected). Female carriers can have isolated or combined corpus callosum agenesis, epilepsy, and/or mental retardation.

XLAG syndrome is also associated with mutations of the *ARX* gene. Affected boys have lissencephaly, corpus callosum agenesis, facial dysmorphic features, ambiguous genitalia, thermoregulation troubles, and severe epilepsy, which can begin prenatally. *ARX* gene mutations are implicated in a wide spectrum of X-linked disorders extending from mild forms of X-linked mental retardation without apparent brain abnormalities to severe lissencephaly. Phenotypes include corpus callosum agenesis with mental retardation, X-linked West syndrome, and Partington syndrome (hand dystony). A phenotype-genotype correlation has not been established.

The *ARX* gene is expressed mainly in telencephalic structures. In adults, *ARX* gene expression becomes restricted to a population of GABAergic neurons.[91] *ARX* seems to be implicated in interneuron migration from the ganglionic eminence (future thalamus); however, its role in cell differentiation and neuronal migration needs to be further clarified.

Lissencephaly with Cerebellar Hypoplasia

Lissencephaly with cerebellar hypoplasia (LCH) is a heterogeneous group of lissencephalies associated with a cerebellar hypoplasia preferentially of the vermis and hemispheres that display sulci. A temporary classification comprising eight subtypes has been proposed. While the phenotype of type A LCH is caused by *LIS1* or *DCX* gene mutations, patients with type B LCH have/display *RELN* gene mutations.[50] The latter lissencephaly is more severe than type A LCH but has a rostrocaudal gradient similar to that seen in patients with *DCX* gene mutations. The cortex is quite thick (5 to 10 mm), while the cerebellum is hypoplastic and smooth.

Further genes responsible for other forms of LCH are unknown. Type C LCH patients usually have a cleft palate. Type D LCH patients (patients with Barth syndrome) display a neuropathology that includes massive brain, cerebellum, and corticospinal tract hypoplasia; their cortex is thick (10 to 20 mm). Type E is close to type A LCH, but with a marked gradient from frontal agyrya to occipital pachygyrya. Type F LCH includes a corpus callosum agenesis. Moreover, two new types of LHC have been reported: LCH with corpus callosum agenesis and cerebellar dysplasia and a subtype with cerebellar hypoplasia, Dandy Walker malformation, and myoclonic epilepsy.

Syndromic Lissencephaly

Two types of lissencephalies are included in the group of syndromic lissencephalies: lissencephalies associated with other neurologic abnormalities (e.g., lissencephaly/pachygyria associated with peripheral demyelinating axonopathy) and lissencephalies observed in syndromes of multiple malformations (in which lissencephaly is generally inconstant and not necessary for diagnosis). Among these syndromes, craniotelencephalic dysplasia (extensive craniosynostosis, microphthalmy, encephalocele), Warburg micro syndrome (corpus callosum agenesis, microphthalmy, microcephaly, cataract, dysmorphic features), Goldenhar syndrome (hemifacial microsomia, branchial arch development abnormalities, hemifacial microsomia, microtia) or Baraitser-Winter syndrome (hyperthelorism, ptosis, coloboma, pachygyria/lissencephaly with a frontal predominence) have been reported.

COBBLESTONE LISSENCEPHALIES (TYPE II LISSENCEPHALIES)

Cobblestone lissencephalies are characterized by a pachygyric or granular brain appearance with shallow sulci and hypomyelination with subcortical cystic cavitations. Lateral and third ventricle dilation, which can be severe, vermis hypoplasia, or general cerebellar and brainstem hypoplasia with small pyramids can be observed. Additional brain anomalies such as hypoplasia/agenesis of corpus callosum, occipital encephalocele, and Dandy-Walker malformation have been described. Hemispheres can be merged on the median line by gliosis. The cortex is thickened (7 to 10 mm), disorganized, and invaded by gliovascular fascicles. White matter contains many heterotopic neurons. Typically, the brain is surrounded by a neurofribroglial envelope, which is not observed in classic lissencephalies and which induces a bumpy (hence “cobblestone”) rather than smooth aspect to the cortical surface. The cortical development defect occurs most likely between 6 and 24 weeks of gestation. Many neurons migrate too far through a defective glial-limiting membrane into the subpial space, that is, beyond the cortical plate. Cobblestone lissencephalies are linked to abnormal O-glycosylation of alpha dextroglycan. POMT1 (9q34 locus) and POMT2 genes encode the two O-mannosyltransferases proteins 1 and 2 (POMT1, POMT2). POMGnT1 encodes an O-mannosyl-beta-1,2-N-acetylglucosaminyltransferase. The FCMD gene on chromosome 9q31 (FKTN) encodes the fukutin protein.

Clinically, cobblestone lissencephalies are observed in three autosomal recessive syndromes, which have been shown to display a significant overlap on the basis of recent molecular genetic discoveries. The incidence of cobblestone lissencephalies is not known, but is most likely around 1 case in 100,000 live births.

Walker Warburg syndrome (WWS) is the most common and the most severe form of cobblestone lissencephaly. It is characterized by the combination of brain malformations such as hydrocephalus, agyria, retinal dysplasia, and sometimes occipital encephalocele (HARD+/-E syndrome) with structural eye abnormalities and muscular dystrophy. Newborns die within the first postnatal months. Eye abnormalities include cataracts, microcornea and microphthalmia, retinal dysplasia, hypoplasia or atrophy of the optic nerve, and glaucoma. In 30% of the patients, this phenotype is linked to POMT1 or POMT2 mutations.

The severity of the brain involvement in Fukuyama syndrome is milder than that in WWS and MEB (muscle-eye-brain) syndrome, and the eyes are only occasionally affected severely. MEB syndrome is characterized by eye involvement (congenital myopia and glaucoma, retinal hypoplasia), mental retardation, and structural brain involvement (pachygyria, flat brainstem, and cerebellar hypoplasia).

Fukuyama disease is linked to mutations of the FCDM gene. MEB syndrome is linked to POMGnT1 gene mutations.

TYPE III LISSENCEPHALY

Type III lissencephaly is characterized by severe microcephaly, agyrya, corpus callosum agenesis, cerebellar, basal ganglia hypoplasia, a thin six-layered cortex, and blurred white matter borders. This lissencephaly has been reported in three autosomal recessive syndromes: Neu-Laxova syndrome, Enchara-Razavi-Larroche lissencephaly (microcephaly, corpus callosum agenesis, cystic cerebellum brain stem hypoplasia and fetal akinesia[35]), and a syndrome reported with lissencephaly, severe microcephaly, corpus callosum agenesia, cerebellar hypoplasia, dysmorphic features and punctuate epiphysis. Neuropathologic findings are similar in these three entities and thereby suggest that they are either allelic diseases or linked to genes implicated in the same function or pathway.

X-LINKED PERIVENTRICULAR HETEROTOPIA

The human X-linked dominant periventricular heterotopia is characterized by neuronal nodules lining the ventricular surface (Fig. 40-28). Hemizygously affected males die within the embryonic period, and affected females have epilepsy, which can be accompanied by other manifestations such as patent ductus arteriosus and coagulopathy. The gene responsible for this disease, Filamin A gene *FLNA*,[37] encodes an actin-cross-linking phosphoprotein, which transduces ligand-receptor binding into actin reorganization. Filamin A is necessary for locomotion of several cell types and is present at high levels in the developing neocortex.

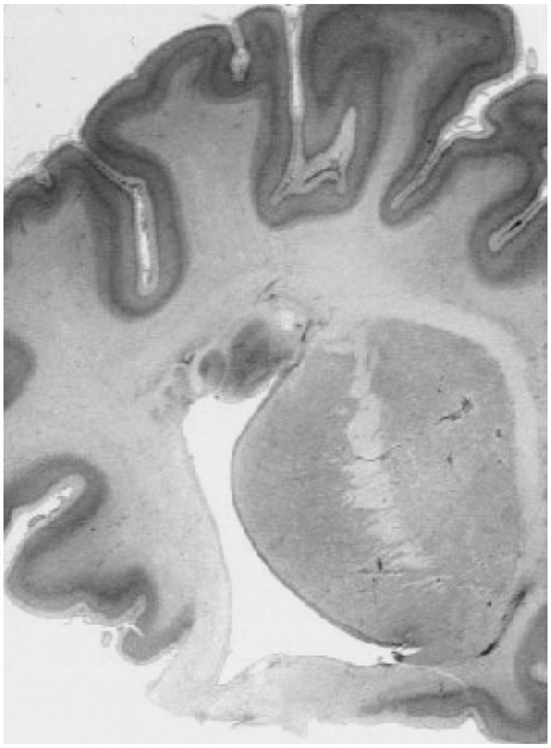

Figure 40–28. Periventricular nodular heterotopias. *(From Barkovich AJ, et al: Formation, maturation, and disorders of brain neocortex,* AJNR Am J Neuroradiol *13:423, 1992, with permission.)*

Null mutations in the *FLNA* gene induce, through a loss-of-function mechanism, X-linked periventricular heterotopias and extraneural abnormalities (cardiac valvular anomalies, propensity to premature stroke, small joint hyperextensibility, gut dismobility, and persistent ductus arteriosus).

ZELLWEGER SYNDROME

The Zellweger cerebrohepatorenal syndrome is a fatal autosomal recessive disease caused by an absence of functional peroxisomes. One hallmark of this human disease is the presence of heterotopic neurons in the neocortex, the cerebellum, and the inferior olivary complex. Patients display severely retarded and/or rapid regression of psychomotor development, facial dysmorphisms, and severe muscular hypotonia; they usually die within the first postnatal months.

Animal models of this human disease have been produced by inactivation of a gene critically involved in peroxisomal assembly.[44] The analysis of these models showed (1) that the migration defect was partially caused by altered NMDA glutamate receptor-mediated calcium mobilization, (2) that this NMDA receptor dysfunction was linked to a deficit in PAF synthesis, and (3) that normal neocortex development requires a normal peroxisomal metabolism in brain and in liver.

EFFECTS OF ENVIRONMENTAL FACTORS ON NEURONAL MIGRATION

Neuronal migration disorders have been described in humans or in animal models after in utero exposure to several environmental factors, including infection with cytomegalovirus or toxoplasmosis (Fig. 40-29), ethanol (Fig. 40-30), cocaine, or ionizing radiation.[43] In most cases, the mechanisms by which these factors disturb neuronal migration remain unclear. Cocaine exposure during gestation has been shown to disturb neuronal migration and cortical addressing both in mice and monkeys. Cocaine exposure in mice was also shown to specifically decrease GABA neuron migration from the ganglionic eminence to the cerebral cortex but not to the olfactory bulbs, suggesting a degree of specificity in the effects of cocaine on neuronal migration. In the human fetal alcohol syndrome, neuronal molecular ectopias have been described in several cases although this sign is not restricted to this syndrome. (See also Chapter 12.) Animal studies have identified abnormalities of radial glia and disturbances of transformation of radial glia into astrocytes.

Disorders of Central Nervous System Organization and Maturation

Disorders involving subplate neurons, axonal and dendritic growth, synaptogenesis and synaptic stabilization, programmed cell death, and glial proliferation and differentiation are likely to have a major impact on brain functions. Unfortunately, little is known about these disorders, largely because the tools to investigate these steps adequately are usually not available even with postmortem tissues. The clinical consequences are rarely obvious in the neonatal

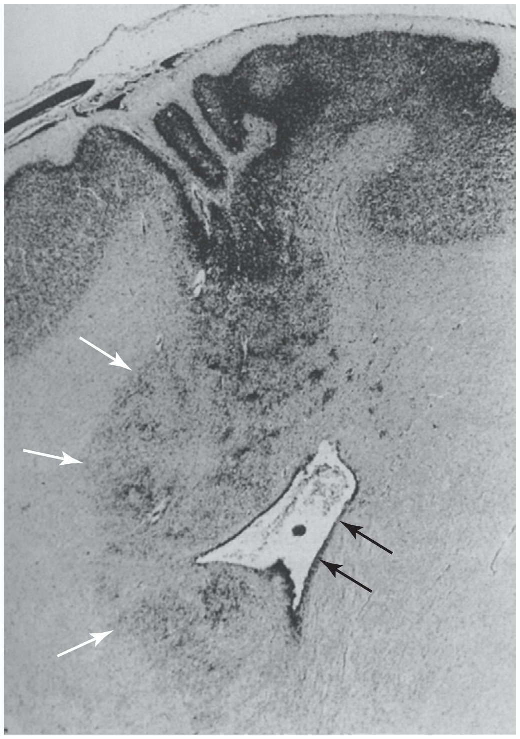

Figure 40–29. Combined polymicrogyria, white matter cystic lesion *(black arrows)* and white matter heterotopic neurons *(white arrows)* in a case of congenital toxoplasmosis. *(From Barkovich AJ, et al: Formation, maturation, and disorders of brain neocortex,* AJNR Am J Neuroradiol *13:423, 1992, with permission.)*

period and usually occur later in life. These disorders can be schematically classified into primary (e.g., idiopathic mental retardation, Down syndrome, fragile X syndrome, Angelman syndrome, Rett syndrome, neurofibromatosis type I, tuberous sclerosis [Bourneville disease], Coffin-Lowry syndrome, Rubinstein-Taybi syndrome, Duchenne muscular dystrophy, thyroid deficiency, and autism) or potentially acquired (e.g., malnutrition deficiencies or effects of prematurity and related environmental factors, including therapeutic and illicit drugs, such as cocaine, acting on the CNS and inducing organizational disorders).[60,119] In most of these disorders, several steps of brain development are affected, such as cortical lamination, dendritic branching and arborization, synaptic contacts, axonal development, and myelination. For example, in tuberous sclerosis, neuronal proliferation and later glial differentiation and proliferation are disturbed.

PART 2

White Matter Damage and Encephalopathy of Prematurity

Petra S. Hüppi and Pierre Gressens

Brain injury in the premature infant is composed of multiple lesions, principally described as germinal matrix intraventricular hemorrhage (IVH), posthemorrhagic hydrocephalus (PHH), and periventricular leukomalacia (PVL). With the reduction of the incidence of IVH and PHH, the third entity now appears to be the most important brain lesion[88,107] determining the neurodevelopmental outcome of premature infants. Periventricular leukomalacia has classically been described as a disorder characterized by multifocal areas of necrosis, forming cysts in the deep periventricular cerebral white matter, which are often symmetric and occur adjacent to the lateral ventricles. These focal necrotic lesions correlate well with the development of spastic cerebral palsy in infants with very low birthweight (VLBW). With the advances in neonatal care and survival at increasingly low gestational ages, a large number of infants with VLBW is now seen with mild motor impairment and often considerable cognitive and behavioral deficits,[103] which may relate to a more diffuse injury to the developing brain.

This chapter presents the current concepts of brain injury to the immature brain, which has recently been termed *encephalopathy of prematurity*,[108] summarizing the old and new neuropathologic findings, mechanisms of pathogenesis through animal models, and the characteristics of this type of lesion in modern neuroimaging.

NEUROPATHOLOGY OF WHITE MATTER INJURY

Historical View

Congenital encephalomyelitis was the term first used by Virchow in 1867 to describe a disease in newborns who demonstrated pale, softened zones of degeneration within the periventricular white matter at autopsy. Microscopically, these lesions were characterized by glial hyperplasia with the presence of foamy macrophages and signs of tissue destruction with necrosis. Interestingly, Virchow related the disease to acute infection, in that many of the cases were seen in infected mothers.[106] Clinically he suggested that these lesions might be related to a disease described earlier by Little,[60] in which the patients suffered from spasmodic limb contractures, diplegia, and mental retardation, occasionally with an additional epileptic condition. Parrot, in 1873, first linked the pathologic entity to premature birth and proposed that the lesions were due to a particular vulnerability of the immature white matter as a result of nutritional and circulatory disturbances resulting in infarction.[82] Much later, Rydberg again proposed a hemodynamic etiology with a reduction of cerebral blood flow to the vulnerable regions of the immature white matter.[94] Banker and Larroche in 1962 first introduced the term *periventricular leukomalacia* to define this characteristic lesion they found in 20% of autopsies of infants who died before 1 month of age. They described the macroscopic and microscopic neuropathology in more detail.[9]

Periventricular Leukomalacia

MACROSCOPIC NEUROPATHOLOGY

The topography of the lesions as described was uniform, primarily affecting the white matter in a zone within the subcallosal, superior fronto-occipital and superior longitudinal fasciculi, the external and internal border zone of the temporal and occipital horn of the lateral ventricles, and some parts of the corona radiata.[31] These areas appeared pale, usually bilateral, but without definite symmetry (Fig. 40-31). Although not unanimously accepted, it has been noted that the anatomic distribution of PVL correlates with the development of perforating medullary arteries and areas that represent arterial border or end zones that arise between ventriculopetal and ventriculofugal arteries within the deep white matter (Fig. 40-32).[47] Immunohistochemical studies further confirm a low vessel density in the deep white matter between 28 and 36 weeks' gestation, whereas in the subcortical white matter, the vessel density is low, between 16 and 24 weeks, and thereafter increases (Fig. 40-33).

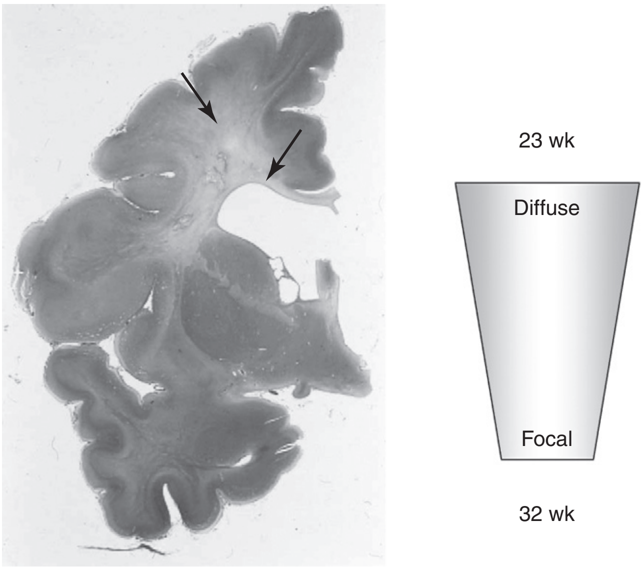

Figure 40–31. See color insert. Neuropathology showing periventricular lesions primarily affecting the white matter and characterized by pale softened zones of degeneration (hematoxylin preparation) *(left arrow)* and thinning of the corpus callosum with ventriculomegaly *(right arrow)*. Lesions detected in infants with very low gestational age at birth tend to be diffuse with more focal cystic lesions in infants with higher gestational age at birth.

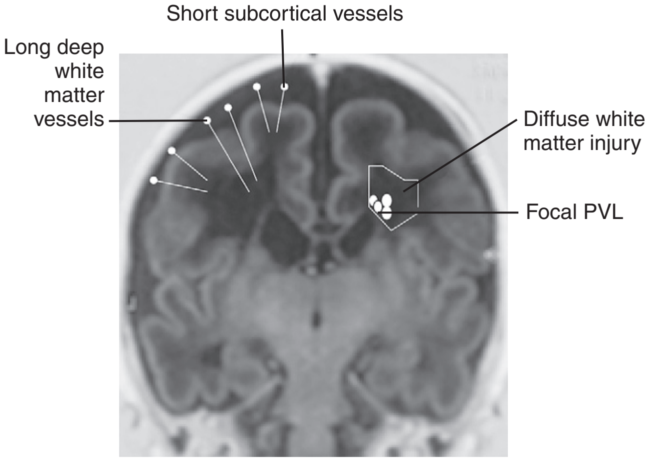

Short subcortical vessels
Long deep white matter vessels
Diffuse white matter injury
Focal PVL

Figure 40–32. Schematic representation of vascular supply characterized by short subcortical end-arteries and long deep end-arteries and their relation to the diffuse and focal component of immature white matter injury (according to Rorke LB: Anatomical features of the developing brain implicated in pathogenesis of hypoxic-ischemic injury, *Brain Pathol* 2:211, 1992). PVL, periventricular leukomalacia.

MICROSCOPIC NEUROPATHOLOGY

The earliest recorded changes were of coagulation necrosis of all cellular elements with loss of cytoarchitecture and tissue vacuolation. Axonal swelling and intense activated microglial reactivity and proliferation were observed as early as 3 hours after insult. In addition, in the periphery of these focal lesions, a marked astrocytic and vascular endothelial hyperplasia characterized the brain tissue reaction at the end of the first week. After 1 to 2 weeks, macrophage activity with characteristic lipid-laden macrophages was predominant over the astrocytic reactivity, with progressive cavitation of the tissue and cyst formation thereafter. During subacute and chronic stages of PVL, swollen axons calcify, accumulate iron, and degenerate, particularly at the periphery of the injured zone. Additional minor changes were also found within the gray matter with

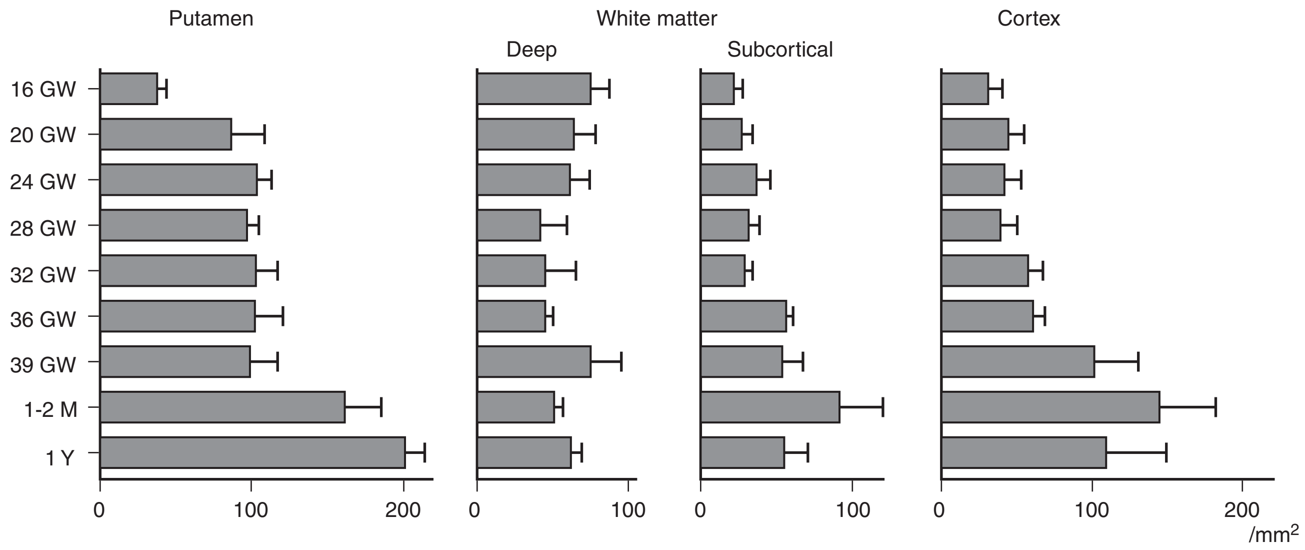

Figure 40–33. Developmental changes in vessel density in the human brain illustrate decrease in vessel density in long deep white matter arteries between 28 and 36 weeks. Note the low density of subcortical end-arteries before 32 weeks of gestation (GW). *(From Miyawako T, et al:* Early Human Dev *53:2025, 1998, reprinted with permission.)*

some diffuse neuronal loss, especially in lower cortical layers, the hippocampus in the cerebellar Purkinje cell layer. Since these early studies, many conventional neuropathology studies have noted a widespread diffuse central cerebral white matter astrocytosis, often with abnormal glial cells, which were called *perinatal telencephalic leukoencephalopathy*. From these studies, Leviton and Gilles introduced for the first time a differentiation between focal and diffuse white matter damage.[56]

NEW NEUROPATHOLOGIC INSIGHTS

This diffuse white matter damage is macroscopically characterized by a paucity of white matter, thinning of the corpus callosum, and in later stages, ventriculomegaly and delayed myelination.[33,56] With the use of immunocytochemical techniques, the assessment of autopsy tissue has allowed further localization of cell-specific injury in white matter damage. Deep periventricular white matter is prone to focal necrosis regionally consistent with the presumed vascular end zones/border zones, whereas in the peripheral white matter, diffuse injury could be characterized by preferential death or injury of late oligodendrocyte progenitors and immature oligodendrocytes, or pre-OLs (see Part 1).[8]

Vulnerability of Oligodendroglia Cell Line

Several lines of evidence implicate damage to immature oligodendrocytes during a specific window of vulnerability as a significant underlying factor in the pathogenesis of PVL (see Models of Encephalopathy, later). Oligodendrocyte progenitor cells proliferate and die by programmed cell death (see Part 1) regulated by trophic factors such as platelet-derived growth factor (PDGF) and insulin-like growth factor (IGF). The activation of cytokine receptors on the surface of oligodendrocytes can lead to the death of these cells. Studies in vitro have shown that the inflammatory cytokines TNF-α and interferon-gamma are toxic to cultured oligodendrocyte progenitor cells.[4] Selective injury to oligodendrocytes is mediated by induction of "death" receptors such as Fas on the surface of oligodendrocytes. Direct axonal contact appears to be another important factor for the survival of oligodendrocytes.[16] Oligodendrocytes are further susceptible to oxidative damage mediated by free radicals such as reactive oxygen and nitrogen species and as a consequence of the depletion of the main antioxidant glutathione.[6] Injury-induced swelling and disruption to axons within the white matter leads to locally elevated glutamate, which also induces oligodendrocyte cell death and/or injury. Glutamate toxicity depends on the maturational stage of the oligodendrocyte and is mediated via the alpha-3-amino-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor and potentially through N-methyl-D-aspartate (NMDA) receptors.[23,52,54]

Recent experimental data show, on the other hand, an important increase in NG2 (high molecular weight, integral membrane chondroitin sulphate proteoglycan)-positive oligodendrocyte progenitor cells within the area of the injury.[97] The role of this increase in NG2 cells is currently unknown, but this population is distinct from neurons, oligodendrocytes, astrocytes, and microglia. This cell population could comprise multipotent cells capable of differentiating into any other type of cell and playing a role in axonal growth and myelination, and in regeneration after injury with functional integration in neural circuitry.

Microglial Activity

Specific immunocytochemical markers (e.g., CD68) have identified a marked increase of activated microglia in diffuse white matter injury.[38] Microglia are already widely dispersed throughout the immature white matter by 22 weeks' gestation. These cells are fully capable of producing potentially toxic inflammatory mediators, free radicals, and reactive oxygen intermediates.[90] The phagocytic activity of microglia and their capacity for oxidative-mediated injury are potently enhanced by inflammatory mediators (IFN-γ, TNF-α, IL-β, and bacterial lipopolysaccharide, or LPS).[101] Studies of preoligodendrocytes of the same maturational stage as those populated in the immature white matter of the human premature infant show that cells are exquisitely vulnerable to attack by reactive oxygen species (ROS) and reactive nitrogen species (RNS) produced by activated microglia.[71] Presence of activated microglia inducing cell death in immature white matter, both in preoligodendrocytes as well as in astrocytes, has been widely confirmed.[28,102] So far, it also seems that microglia and resident mononuclear phagocytes are the primary sources for the proinflammatory cytokines in PVL brains.[53]

Neuronal/Axonal Damage

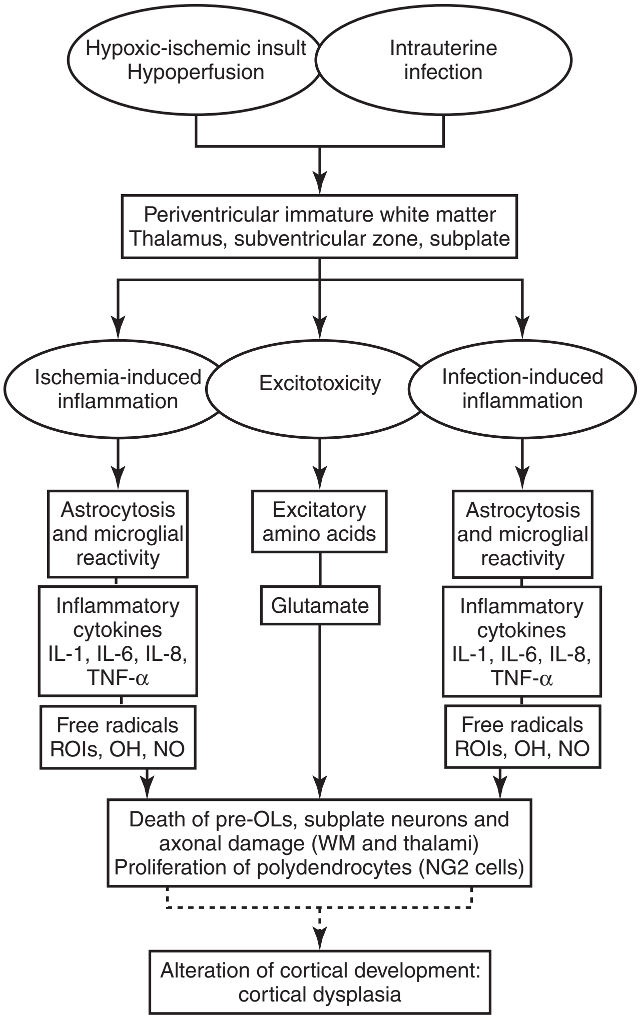
Indirect assessment of axonal damage in classic PVL was done by immunostaining for beta amyloid precursor protein, a neuronoaxonal protein. Immunostaining of damaged axons was predominant in the acute phase of PVL and was no longer detectable in the chronic stage. Swollen axons calcify (probably due to glutamatergic overactivation), accumulate iron, and degenerate; this has been shown to occur without overt coagulation necrosis of all tissue components.[39] Axons from the corticospinal tract, thalamocortical fibers, optic radiation, superior occipitofrontal fasciculus, and the superior longitudinal fasciculus may be affected and result in motor, sensory, visual, and higher cortical function deficits. Thalamocortical projections that course through the white matter develop before the functional development of cortical neurons. Therefore, the ensuing disruption to these circuits and to the subcortical plate may not only affect the function, but also the density, survival, and organization of cortical neurons and the cortex itself (see later).[46]

In addition, there is evidence for death of progenitor cells, not neural stem cells, in the subventricular zone after hypoxia-ischemia.[93] These destructive effects are paralleled with potential trophic reactions such as the proliferation of potentially pluripotent progenitor cells, also called *polydendrocytes*, in the area of injury.[97] These cells are known to differentiate into oligodendrocytes, to a lesser extent into gray matter astrocytes, and potentially even into neurons.[78]

Subplate Damage

Damage to the early developing subplate neurons with their critical role for the organization of the cortical plate (see Part 1 of this chapter) has long been postulated as a possible mechanism by which injury to the immature brain results in long-lasting motor and cognitive deficits.[109] McQuillen and colleagues[70] were able to show specific cell death in subplate neurons after hypoxia-ischemia in very immature animals. Lack of guidance for the thalamocortical connections as a result of a loss of subplate neurons may represent one of the major developmental disturbances after injury to the immature brain.[55]

The current concept of pathogenesis of encephalopathy of prematurity is based on the combination of destructive and developmental disturbances, which are schematically summarized in Figure 40-34.



Hypoxic-ischemic insult
Hypoperfusion
Intrauterine infection
Periventricular immature white matter
Thalamus, subventricular zone, subplate
Ischemia-induced inflammation
Excitotoxicity
Infection-induced inflammation
Astrocytosis and microglial reactivity
Excitatory amino acids
Astrocytosis and microglial reactivity
Inflammatory cytokines IL-1, IL-6, IL-8, TNF-α

MODELS OF ENCEPHALOPATHY OF PREMATURITY: IMPLICATIONS FOR PATHOGENESIS

The etiology of white matter injury and encephalopathy of prematurity in human neonates has been widely described as multifactorial rather than linked solely to cardiovascular instability and hypoxia-ischemia. The many preconceptional, prenatal, perinatal, and postnatal factors potentially implicated in the pathophysiology of these lesions include hypoxia-ischemia, endocrine imbalances, genetic factors, growth factor deficiency, abnormal competition for growth factors, overproduction of free oxygen radicals, maternal infection with overproduction of cytokines and other proinflammatory agents, exposure to toxins, maternal stress, and malnutrition. Although some of these potentially noxious factors may suffice to permanently injure the developing brain, some researchers have developed a "two-hit" hypothesis in which early exposures increase the susceptibility of the brain to subsequent insults (Fig. 40-35).

The development and characterization of distinct yet complementary animal models should help unravel the complex cellular and molecular pathophysiologic mechanisms underlying perinatal white matter lesions and encephalopathy of prematurity. In animal models or in vitro paradigms, the insults most often used to induce white matter damage or oligodendrocyte cell death, respectively, are generally hypoxia, hypoxia-ischemia, infection, inflammatory factors, oxidative stress, or excitotoxic agents. The relevance of white matter damage produced in these animal models to human white matter injury is largely based on neuropathologic data, although some studies are also based on MRI parameters or on neurologic and behavioral deficits.[24]

This section focuses on the most studied models of perinatal white matter damage, highlighting their major contributions to the understanding of the pathophysiology of these lesions. The reader interested in a deeper insight will find more information and a more comprehensive bibliography in published reviews on this topic.[37,72]

Hyoperfusion and Hypoxia-Ischemia

Hypoxic-ischemic or hypoperfusion insults have been used in a large variety of neonatal species including rats, mice, rabbits, pigs, and dogs. In most cases, these insults produce specific gray matter damage (mimicking lesions observed in human full-term infants), which have been the focus of most of these studies, whereas observed white matter damage is generally considered to be an extension of gray matter damage in the most severe cases. However, notable "exceptions" highlight some potentially important features of perinatal white matter damage.

In dog pups, hypoxic-ischemic insult by bilateral carotid ligation selectively induces white matter damage mimicking human PVL.[115] This selective vulnerability of white matter could underlie a genetic predisposition of the dog to white matter hypoxic-ischemic damage. Modern tools of genomics could unravel important genes involved in the pathophysiology of perinatal white matter damage.

In rats, the classic Rice-Vannucci model performed on postnatal day 7 or 9, predominantly leads to gray matter lesions. However, analyses have shown the involvement of the periventricular white matter with the involvement of immature oligodendroglial and progenitor cells.[7,99] More importantly, adaptation of this paradigm to more immature newborn rats (postnatal days 1 or 3) has allowed production of important lesions in the periventricular white matter with relative sparing of the classic intracortical injuries (Fig. 40-36).[70,98] These studies have also highlighted the specific involvement of subplate neurons in brain damage. Altogether, these data obtained in newborn rats further support the notion of an ontogenic window of white matter sensitivity and subplate vulnerability to insults such as hypoxia-ischemia.

Asphyxia of sheep fetuses (around 65% of gestation) has been shown to induce periventricular (focal and diffuse) and subcortical (diffuse) white matter disease, accompanied by acute astrocyte and oligodendrocyte loss, and marked reactive microgliosis.[65] These studies support the concept of the association of focal (e.g., cystic lesions) and diffuse (e.g., diffuse microglial activation) white matter lesions, the pathophysiology of which being potentially distinct. Furthermore, it was shown by microdialysis that white matter glutamate levels were significantly increased following asphyxia, supporting a role of excitotoxicity in the pathogenesis of such white matter lesions (see later).[62]

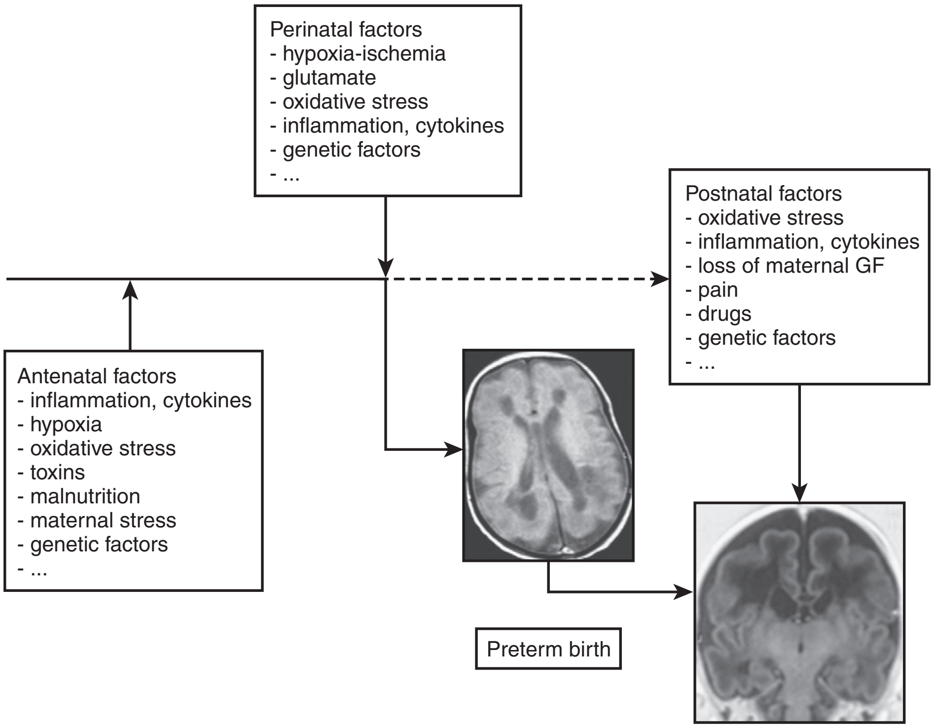

Figure 40–35. Schematic representation of the "multiple-hit" hypothesis in which a combination of two or more environmental or genetic factors occurring during the prenatal, perinatal, or postnatal period induces or modulates brain lesions. GF, growth factors.

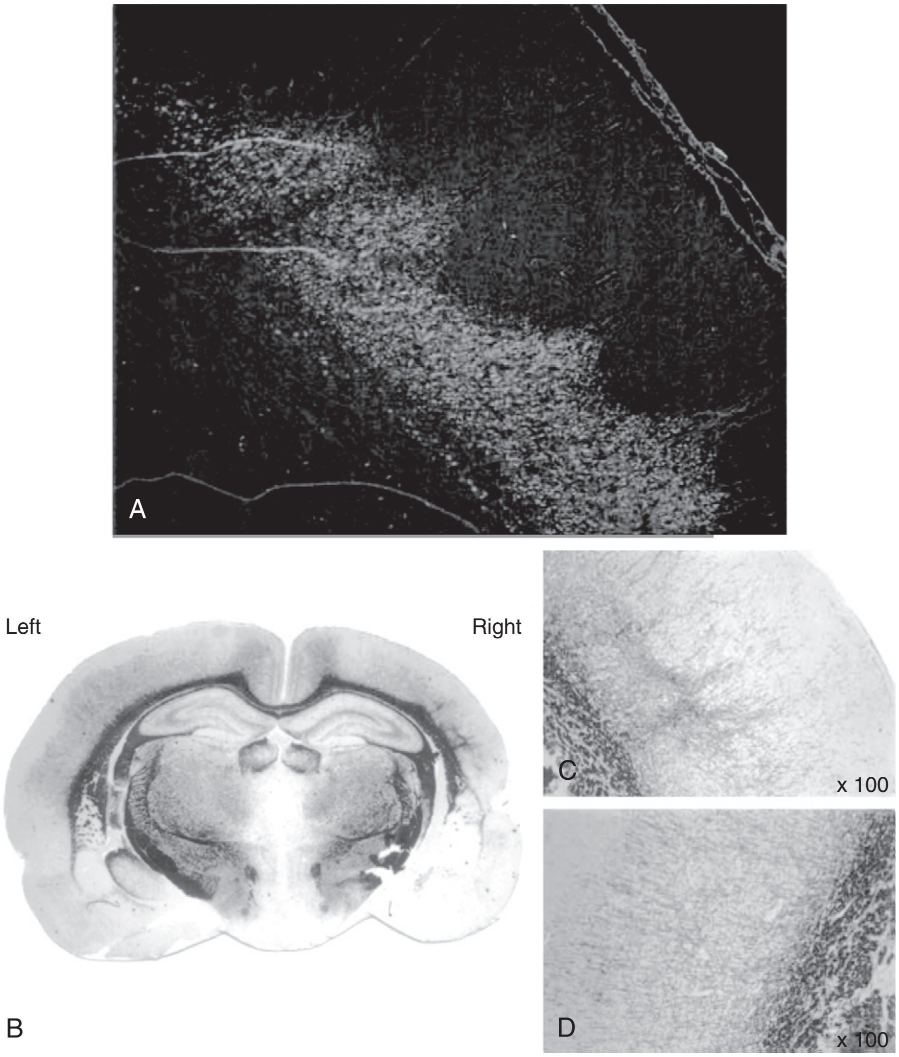

Figure 40–36. Pattern of injury after hypoxic-ischemic injury in the P3 rat brain **A**, Degenerating neurons 24 hours after hypoxic-ischemic insult at P3 stained with Fluoro-Jade. Ipsilateral brain with severe damage: a columnar aspect of positive cells is present with confluence of positive cells in the deep layers IV-VI (100×). The outer layers I-III remained unaffected. **B**, Myelin basic protein immunostaining of the brain at P21 after hypoxic-ischemic injury at P3. Coronal section of brain at the level of the dorsal hippocampus (10×). A reduction of the cortical and myelinated areas in the ipsilateral right hemisphere extending from the cingulum to the rhinal sulcus. At 100×, the alteration of the myelin pattern in the deep cortical layers is shown in the ispsilateral right cortex (**C**) when compared with the left normal cortex (**D**).

Exposure of pregnant rats[11] or postnatal rat pups[104] to hypoxia induces pathologic changes in the periventricular white matter which are reminiscent of human periventricular leukomalacia, with inflammation, astrogliosis, and myelination delay in the prenatal model, and white matter atrophy, ventriculomegaly, and alteration of synaptic maturation in the postnatal paradigm. Although the initial insult is a pure hypoxia, the observed effects are likely the result of the combination of different mechanisms, such as hypoperfusion, ischemia, inflammation, and/or oxidative stress induced by the protracted hypoxia and the subsequent reoxygenation phase.

Infection and Inflammation

Systemic administration of LPS to immature cats, dogs, or rabbits induces white matter lesions. Systemic administration of LPS can induce a marked systemic inflammation and immune changes in the central nervous system such as an increased expression of CD14. Furthermore, high doses of LPS can induce hypotension, hypoglycemia, hyperthermia, and lactic acidosis, all potential factors predisposing to brain damage. However, low doses of LPS, which do not induce significant hypotension, have also been shown to induce white matter damage in fetal sheep.[37,64] In fetal sheep, the comparison of white matter damage induced by cord occlusion and by LPS injection, revealed distinct patterns of microglia-macrophage activation, suggesting separate or partly separate underlying mechanisms.[64] On the other hand, systemic administration of LPS to newborn rats failed to induce detectable white matter lesions, although increased cytokine production and microglial activation were observed in the white matter.[15,30,113] These data suggest species differences that might be linked to species-related genetic susceptibility of the developing white matter to infectious-inflammatory factors. Interestingly, in vitro studies have shown that macrophages are necessary for LPS to induce preoligodendrocyte cell death.

Live infectious agents have also been used by a few research groups to produce models of white matter lesions. In pregnant rabbits, ascending intrauterine infection with *Escherichia coli* caused focal white matter damage in 6% of live fetuses,[114] whereas direct inoculation of *E. coli* in the uterine cavity combined with early antibiotics produced focal white matter cysts in about 20% of live fetuses and diffuse white matter cell death in almost all live fetuses (Fig. 40-37).[22] Cystic lesions are accompanied by macrophage-microglia activation and reactive astrogliosis, while diffuse white matter cell death does not induce such glial responses. These results suggest that these two types of brain damage have distinct pathophysiologic mechanisms.

In addition, a recent study has shown that infection of pregnant mice with *Ureaplasma parvum*, an organism frequently isolated in chorioamnionitis, induces central microgliosis and disrupted brain development as detected by decreased number of calbindin-positive and calretinin-positive neurons in the neocortex as well as myelination defect in the periventricular white matter.[79]

Finally, intrauterine inoculation of Border disease virus to pregnant sheep induces decreased expression of white matter molecules, including myelin basic protein in the fetuses.[3] However, the virus also infects the thyroid and the pituitary gland, raising the question of the precise etiology of the white matter damage (low thyroid hormones versus infectious-inflammatory insult).

Excitotoxicity and Oxidative Stress

Glutamate can act on several types of receptors including NMDA, AMPA, kainite, and metabotropic receptors. Excess release of glutamate has been suggested to represent a molecular mechanism common to some of the risk factors for brain lesions associated with cerebral palsy. In keeping with this possibility, injection of glutamate agonists into the striatum, neocortex, or periventricular white matter of newborn rodents (rats, mice, or hamsters), rabbits, or kittens produces, according to the stage of brain maturation, histologic lesions that mimic those seen in humans with cerebral palsy, such as neuronal migration disorders, polymicrogyria, cystic periventricular leukomalacia, and hypoxic-ischemic or ischemic-like cortical and striatal lesions.[1,67,69]

Studies exploring the pathophysiology of these excitotoxic white matter lesions in newborn rodents and rabbits have permitted the following contributions (Fig. 40-38)[89]:

1. Both NMDA and AMPA-kainate agonists can induce periventricular cystic white matter lesions.

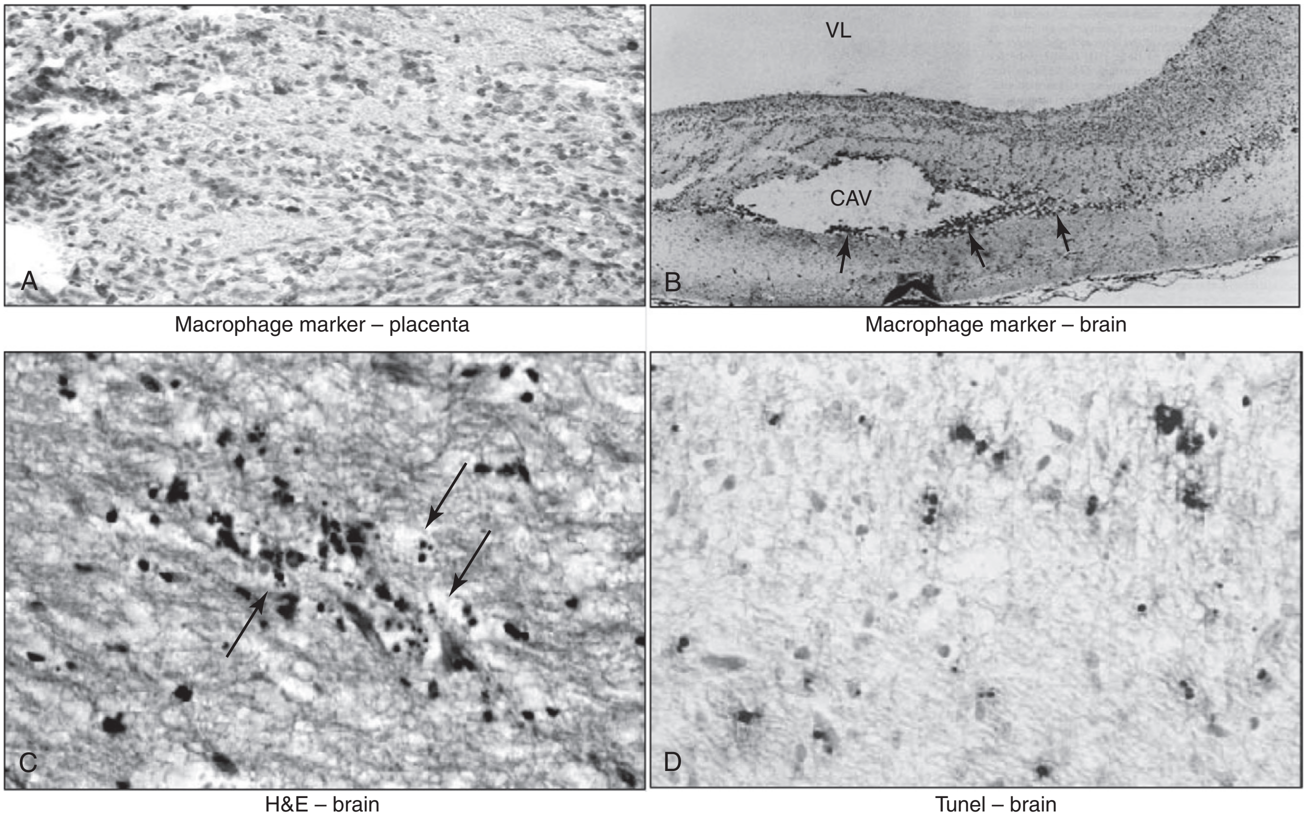

Figure 40–37. See color insert. Intrauterine infection with *Escherichia coli* in pregnant rabbits induces a combination of placental and brain abnormalities. **A**, Macrophage activation is observed in all placentas. The numerous red cells correspond to activated macrophages labeled with a specific antigen. **B**, Focal cystic periventricular white matter lesions with macrophage activation are detected in some fetuses. Brown cells identified by *arrows* correspond to activated macrophages/microglia labeled with a specific antigen. CAV, cystic lesion; VL, lateral ventricle. **C** and **D**, Diffuse white matter cell death without detectable inflammatory response is observed in all fetuses on hematoxylin-eosin stained sections (**C**, *Arrows* point to examples of apoptotic nuclei in the periventricular white matter) and on Tunel (a marker of fragmented DNA and of accompanying cell death)-stained sections (**D**, Purple-blue nuclei correspond to diffusely distributed dying white matter cells). *(From Debillon T, et al: Intrauterine infection induces programmed cell death in periventricular white matter,* Pediatr Res *47:736, 2000, and Patterns of cerebral inflammatory response in a rabbit model of intrauterine infection-mediated brain lesion,* Brain Res Dev Brain Res *145:39, 2003, with permission.)*

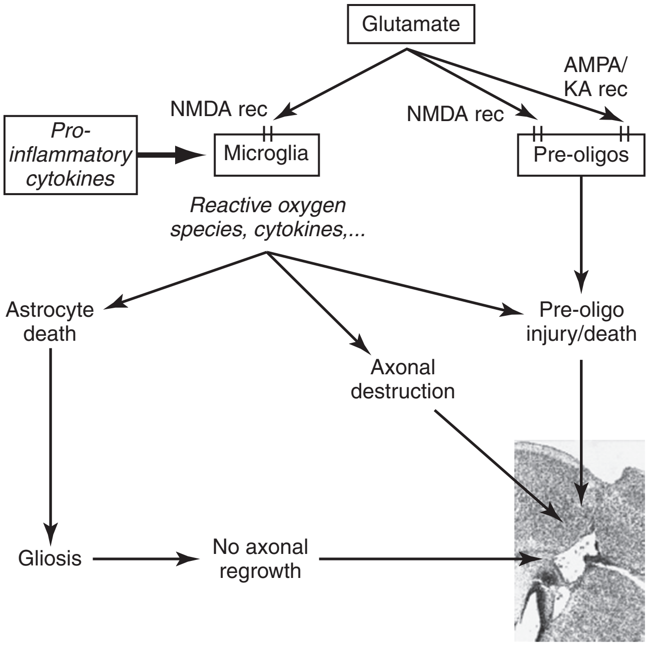

Figure 40–38. Schematic representation of the potential cellular and molecular pathways by which excess release of glutamate and proinflammatory cytokines may lead to white matter lesions. AMPA, alpha-3-amino-hydroxy-5-methyl-4-isoxazole propionic acid; KA, kainate; NMDA, N-methyl-D-aspartate; oligo(s), oligodendrocyte(s); rec, receptors.

2. NMDA receptor–mediated white matter lesions involve an early microglia-macrophage activation and astrocyte cell death, whereas AMPA-kainate receptor–mediated lesions involve preoligodendrocyte cell death. In addition, NMDA receptors expressed by preoligodendrocytes could participate in the injury of these preoligodendrocytes.
3. The periventricular white matter of newborn rodents and rabbits exhibits a window of susceptibility to excitotoxic insults.
4. Transient expression of NMDA receptors on white matter microglia-macrophages and transient expression of high levels of AMPA-kainate receptors on preoligodendrocytes are likely important factors to explain the window of sensitivity of the white matter to neonatal excitotoxic insults.
5. The study of NMDA receptor-mediated white matter lesions in newborn rabbits revealed that the excitotoxic white matter lesion extended into the subplate but not in the overlying neocortical layers. Based on the use of antioxidant molecules, excitotoxic white matter lesions involve excess production of reactive oxygen species, which play an important role in the pathophysiology of the lesions.

Extensive in vitro studies have confirmed the exquisite susceptibility of preoligodendrocytes to AMPA-kainate agonists and to oxidative stress.[52]

Combined Insults

In order to further support the hypothesis of a multifactorial cause of perinatal brain damage (see Fig. 40-35), different groups have combined insults in newborn rodents.

Pretreatment of newborn mice with systemic proinflammatory cytokines (e.g., IL-1β, IL-6, or TNFα) before an excitotoxic insult significantly exacerbates excitotoxic white matter lesions, demonstrating a causative link between circulating proinflammatory cytokines and white matter damage.[27] Preliminary results suggest that this effect of proinflammatory cytokines is more pronounced with NMDA receptor agonists when compared with AMPA-kainate receptor agonists (see Fig. 40-38). The precise mechanism by which these systemic cytokines act on white matter excitotoxicity remains to be determined but could potentially involve activation of brain cyclooxygenase (COX) or activation of microglia with increased white matter production of reactive oxygen species and cytokines.

Similarly, systemic pretreatment with IL-9, a Th2 cytokine, was shown to exacerbate NMDA receptor-mediated white matter lesions.[27,84] The mechanism of IL-9 toxicity involves brain mast cell degranulation and excess release of histamine. Interestingly, increased circulating levels of IL-9 around birth had been demonstrated in a subgroup of human infants who later developed cerebral palsy.[77] Recently, chronic mild stress of pregnant mice was shown to induce a significant exacerbation of excitotoxic white matter lesions in pups.[89a]

LPS was also used to sensitize the newborn brain to hypoxia-ischemia. A low dose of this endotoxin, given 4 hours before a mild hypoxic-ischemic insult in the P7 rat, induced extensive brain damage, while each insult given separately did not induce any detectable brain lesion.[30]

Recent years have seen the emergence of several experimental paradigms to study white matter diseases of the preterm infant. These animal models have permitted identification of some of the potentially key cellular players (e.g., preoligodendrocytes, microglia-macrophages) and molecular players (e.g., glutamate, cytokines and other inflammatory mediators, reactive oxygen species) involved in the pathophysiology of perinatal brain damage. These studies have also delineated potential targets for neuroprotection. Future studies should incorporate imaging and behavioral studies to facilitate comparison with the human situation. Although it is clear that studies with rodents, due to their cost and availability, are absolutely necessary to generate and test multiple hypotheses, the use of larger models such as sheep, pigs, and monkeys will remain a key for testing in a more reliable fashion the relevance of the obtained data for the human situation.

NEUROIMAGING OF WHITE MATTER INJURY

Neonatal Sonography

Neonatal sonography is the one major bedside technique to image the neonatal brain. Leviton and colleagues postulated in 1990 that ultrasonographic white matter echodensities and echolucencies in infants with low birthweight predicted later handicap more accurately than any other antecedent.[57]

Unlike intraventricular hemorrhage, damage to the white matter can have different appearances and depending on the timing of the injury, the imaging characteristics can be nonspecific with generally an increase in echogenicity in the acute phase of the injury (Fig. 40-39). In clinical practice, at least in the older preterm infant, the condition of white matter is judged by its echogenic potential as compared with that of the choroid plexus. Generally, the echogenicity found in early periventricular leukomalacia is similar in intensity to that of the choroid plexus. The echogenicity is bilateral, but slightly asymmetric in appearance, can be sharply delineated, and may have nodular components. This has to be differentiated from normal peritrigonal flaring, which is perfectly symmetric and has a radial appearance. Evolution of such hyperechogenicity can be twofold, either complete disappearance or evolution into cysts and/or ventricular dilation. Cyst formation is typical during the second week (10 to 40 days) after the insult. de Vries and associates[26] postulated an ultrasound-based classification for PVL of four grades. Increasing grades are associated with increasing neurodevelopmental handicap. Grade I is defined as transient (persisting less than 7 days) periventricular densities without cyst formation. If cysts develop and are few in number, localized primarily in the frontal and frontoparietal white matter, this is classified as grade II. When they are widespread and extend into the parieto-occipital region, they are referred to as grade III; these may grow and gradually disappear, leaving an irregularly dilated lateral ventricle. Grade IV cysts are present all the way into the subcortical area and resemble porencephaly (Table 40-3). In a pooled analysis based on data from 15 published studies, 11% of infants with small, 35% of those with medium, and 60% of those with large ultrasound-defined white matter echolucencies had an intelligence or developmental index less than 70,[40] which outlines the importance of potentially associated microstructural alterations in cortical development after white matter injury. Ultrasound can be viewed as the ideal mode of imaging to detect cystic PVL, but has very limited value for detecting diffuse white matter injury and the processes leading to encephalopathy of prematurity as shown in studies comparing neonatal sonography with MRI.[18,25,49,91]

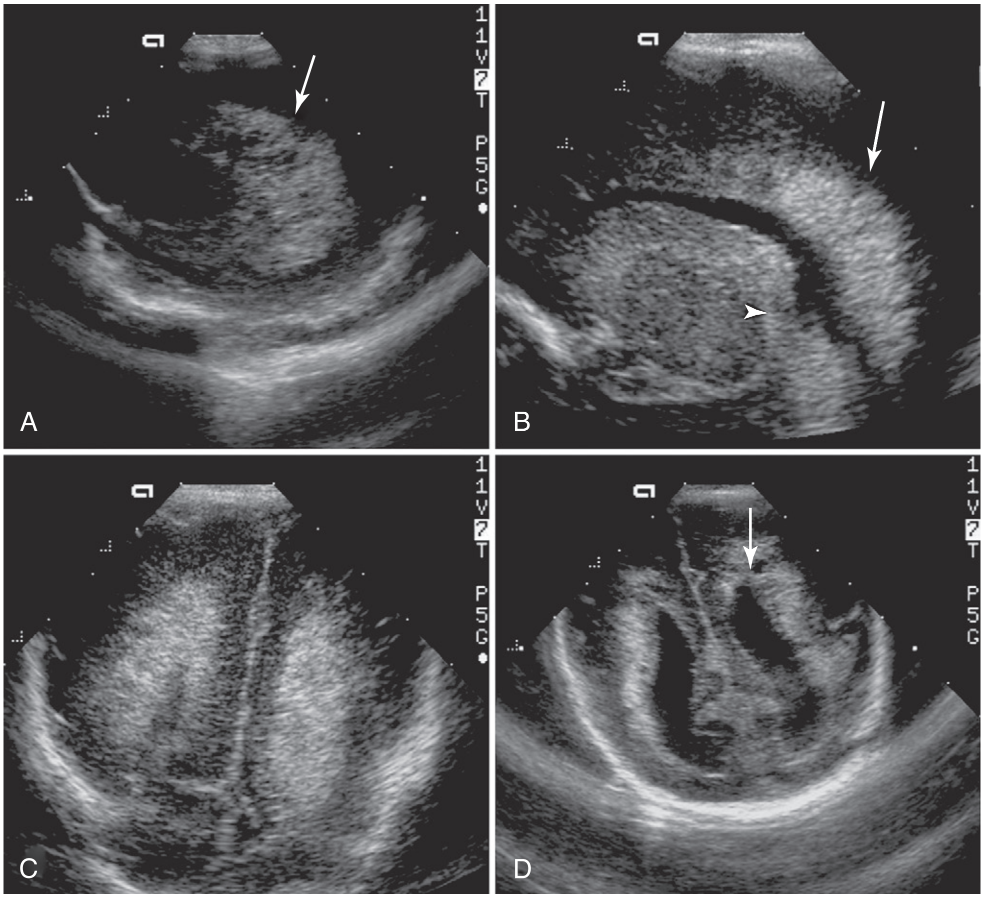

Figure 40–39. Ultrasound scans of periventricular echodensity in a preterm infant born at 27 weeks' gestational age with premature rupture of membranes and neonatal sepsis. Note: bilateral echodensities in sagittal view at 5 days of age (**A**, **B**; *arrows*) with echogenicity of similar intensity to echogenicity of choroid plexus (**B**; *arrowhead*). **C**, Bilateral echodensities in coronal view. **D**, Cystic transformation noted by echolucency developing at 12 days in sagittal view (*arrow*).

TABLE 40–3 Ultrasound Classification of Periventricular Leukomalacia[26]

Grade I	Transient periventricular echodensities (PVE) (<7 days)
Grade II	PVE evolving into localized frontoparietal cystic lesions
Grade III	PVE evolving into extensive periventricular cystic lesions
Grade IV	Echodensities evolving into extensive periventricular and subcortical cysts

Classification needs longitudinal assessment with daily to weekly ultrasound evaluations.

Conventional Magnetic Resonance Imaging

Conventional T1- and T2-weighted imaging can show signal abnormalities in the periventricular white matter that are different from the cystic lesions detected by ultrasound. The typical conventional MRI pattern in the subacute phase consists of punctate periventricular areas of T1 signal hyperintensities and T2 signal hypointensities (Fig. 40-40). The precise neuropathologic correlate of these signal abnormalities is not completely known, but may be due to some hemorrhagic component of the lesions. The abnormal signal most likely represents the cellular reaction of glial cells and macrophages, which are known to contain lipid droplets (see microglia activation), accounting for the high signal intensity in T1-weighted MR images.[95] These abnormalities have been associated with the presence of markers of oxidative stress in the cerebrospinal fluid (CSF).[48] Most of these lesions disappear by term age and their significance for later neurodevelopmental problems is still unclear.[29]

Conventional MRI features of chronic white matter injury in the immature brain are characterized either by cysts comparable to ultrasound, but also and more importantly, by a persistent high signal intensity of the white matter in T2-weighted images representing diffuse white matter injury (Fig. 40-41).[43] This imaging characteristic is later associated with thinning of the corpus callosum and loss of white matter volume, resulting in deep prominent sulci (see later). In several studies on the preterm infant brain, diffuse excessive high signal intensity (DEHSI) in the cerebral white matter on T2-weighted imaging was reported to be present in up to 40% to 75% of preterm infants with low birthweight imaged at term (Fig. 40-42).[63] MRI is further ideally equipped to assess delayed myelination. The absence of myelination in the posterior limb of the internal capsule (missing T1 high signal intensity, T2 low signal intensity) at term age is a good indicator of later neuromotor impairment (Fig. 40-43).[2,10,21]

Woodward and associates[112] in a population-based study showed that 21% of preterm infants at term age had MR-defined moderate to severe white matter abnormalities, but an even larger proportion of 49% had gray matter abnormalities characterized by poor cortical development. Furthermore, about half of the preterm infants showed mild white matter abnormalities, and these infants had only marginal mental developmental indices at age 2 years (Table 40-4).

Diffusion Magnetic Resonance Imaging

Diffusion-weighted MR imaging (DWI) or diffusion tensor imaging (DTI) measures the self-diffusion of water. The two primary pieces of information available from DWI studies—water apparent diffusion coefficient (ADC) and diffusion anisotropy measures—change dramatically during development, reflecting underlying changes in tissue water content and cytoarchitecture (see Part 1 of this chapter).

DWI parameters also change in response to brain injury. ADC decreases in acute injury and possible mechanisms leading to this decrease are: decrease in extracellular fluid due to cellular swelling (cytotoxic edema), swelling of mitochondria and reduction of cytoplasmic diffusion, axonal swelling, and other mechanisms such as membrane changes due to fatty acid peroxidation.

Early assessment of periventricular white matter in preterm infants with DWI can reveal bilateral periventricular diffusion restriction similar to the typical distribution of PVL

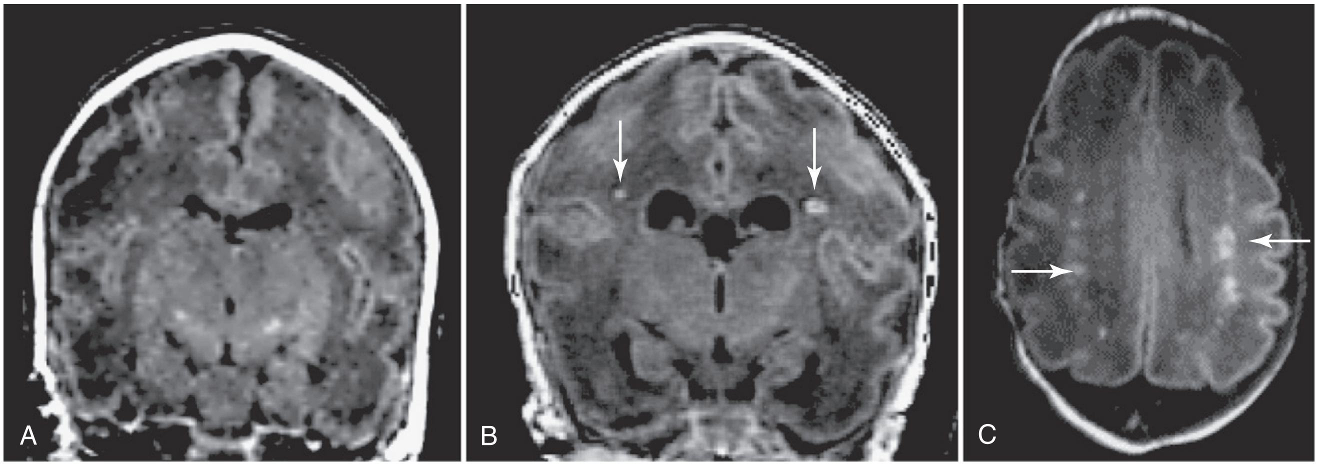

Figure 40–40. Conventional T1-weighted MR images in coronal (**A**, **B**) and axial plane (**C**). **A**, Normal preterm infant at 31 weeks' gestational age. **B**, **C**, Bilateral periventricular lesions with high signal intensities in a preterm infant of 31 weeks' gestational age *(arrows)*.

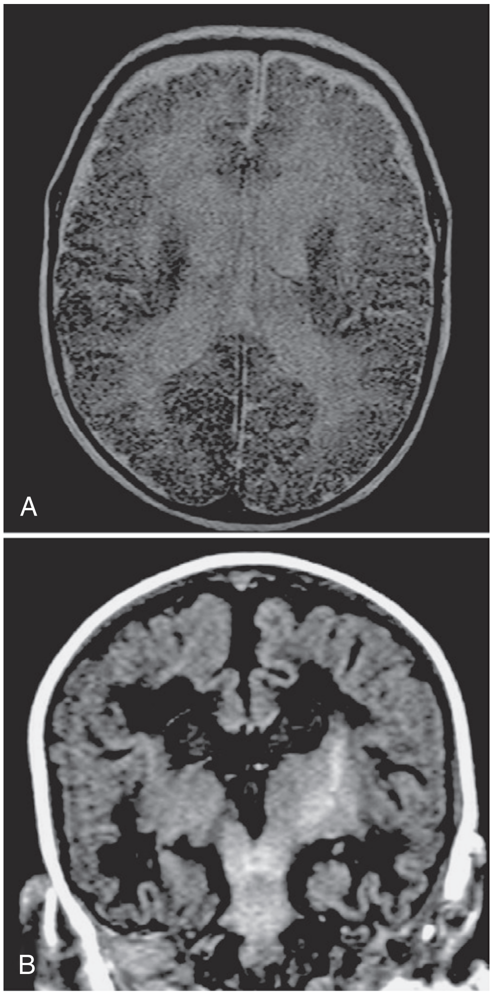

Figure 40–41. Conventional T2-weighted MRI (**A**) and inversion recovery MRI with T1-weighted signal characteristics (**B**) in an ex-preterm infant of 25 weeks' gestational age imaged at 40 weeks' gestational age, with severe bronchopulmonary dysplasia and repetitive episodes of severe hypoxia. **A**, Widespread markedly increased T2 signal intensity in the central white matter. **B**, Low signal intensity on the inversion recovery image in the central white matter, representative of diffuse white matter injury.

when ultrasound and conventional MRI show no or nonspecific abnormalities (Fig. 40-44).[14] A reduced ADC in an otherwise normal preterm brain is considered an early indicator of white matter damage (just as a reduced ADC is seen shortly after the onset of an acute cerebral ischemic lesion in adults). The typical histologic changes in the acute phase of PVL outlined earlier are characterized by some of the same mechanisms leading to restriction of water diffusivity. These changes are responsible for the diffusion changes described earlier in that they considerably change the microstructure of white matter and therefore change water diffusivity.

The chronic phase of white matter injury again is characterized by cyst formation (Figs. 40-45 and 40-46) and by T2-weighted hyperintensities of the white matter or DEHSI for which studies demonstrate higher ADC values in the area of T2 hyperintensities, which confirms the locally higher tissue water content in those areas (see Fig. 40-42).[20,74] These high ADC values are similar to those seen in the very immature healthy white matter; therefore a potential explanation for the failure of ADC to decline from high levels in the extremely premature infant to lower levels in the term infant in the presence of DEHSI might be related to prior injury with destruction of normal cellular elements (i.e., preoligodendrocytes) as discussed in the models of white matter injury.[107] Further quantitative measures of diffusion at term among premature infants with perinatal white matter lesions, when compared with preterm infants without white matter injury, showed lower anisotropy values in the area of the previous injury (i.e., central periventricular white matter), but also in the underlying posterior limb of internal capsule (Fig. 40-47).[44,76] The lower anisotropy in the injured cerebral white matter suggests that white matter fiber tracts were destroyed or their subsequent development was impaired. Whether this effect involves axon bundles per se, their packing density, or their encasement by premyelinating oligodendroglia is unknown. The lower anisotropy in the internal capsule further suggests a disturbance in the development of the descending corticospinal tracts.[42] Fiber tracking is another technique applied to the developing brain to study quantitative assessment of specific pathway maturation in white matter.[110] Berman and coworkers[12] showed significant differences in the maturational changes in fractional anisotropy and transverse diffusion between the motor and the somatosensory pathway in premature infants between 30 and 40 weeks' gestational age. This approach further allowed the measurement of diffusion changes across multiple levels of the functional tract and, therefore, the assessment of myelination progress over a given white matter fiber tract.[12,83]

The subsequent neurologic deficits after cerebral white matter injury are grouped together under the term of cerebral palsy. Structural correlates of cerebral palsy have been assessed using DTI.[41] Tract-specific evaluation of children with cerebral palsy after PVL identified most frequent alterations in white matter fiber tract development in the retrolenticular part of the internal capsule, posterior thalamic radiation, and superior corona radiata, and in commissural fibers of the corpus callosum.[75]

The clinical relevance of injury and related modification of white matter architecture detected in this fashion is not yet known, and long-term follow-up studies of prematurely born children are currently underway linking functional outcome to structural white matter development assessed by DTI.[5,10,19,32,100]

DWI with diffusion tensor analysis has provided new insights into microstructural white matter development and seems to be an ideal tool to assess alteration of white matter pathways in neurologic disease.

Magnetic Resonance Spectroscopy

One of the essential contributors to the progress in noninvasive detection of tissue metabolism and in vivo biochemistry in recent years has been magnetic resonance spectroscopy (MRS), which gives specific chemical information on the biochemistry of numerous intracellular metabolites. The biochemical characteristics of white matter damage in preterm

infants have been studied in vivo using MRS.[35,92] Similar to the high diagnostic value of MRS in term asphyxia, MRS in acute phase immature white matter injury can detect indicators of anaerobic glycolysis with increased intracerebral lactate.[86] Data suggest that white matter damage in the preterm infant studied around term gestational age resulted in high lactate-to-creatinine and high myoinositol-to-creatinine ratios.[92] The increased presence of lactate at this chronic stage was not associated with changes in pH,[92] whereas N-acetylaspartate as a marker of neuroaxonal integrity was reduced in the damaged periventricular white matter.[35] As outlined in part 1 of this chapter on brain development, astrocytes further play a variety of complex nutritive and supportive roles in relation to neuronal metabolic homeostasis. For example, astrocytes take up glutamate and convert it to glutamine. This removal of glutamate from the

extracellular space protects surrounding cells from glutamate excitotoxicity. Glutamate uptake into astrocytes further stimulates glycolysis within the astrocyte with production of lactate that can be used by neurons as energy substrate.[85] Given that chronic phase white matter injury is characterized by widespread cerebral white matter astrocytosis, this change in metabolite composition might be an expression of altered cellular composition and substrate use.

Other metabolites become visible with short echo-time spectroscopy such as the macromolecules/lipids at 0.9 ppm and 1.3 ppm (see Fig. 40-18). These resonances show important changes in adult hypoxia-ischemia[34] and in experimental data on in vitro apoptosis.[13] Preliminary data suggest that these metabolites are also present in acute periventricular white matter injury of the immature brain and might represent metabolites from membrane peroxidation. Consistent with the observation of these resonances, one study found elevated neonatal levels of lipid peroxidation and oxidative protein products in cerebrospinal fluid of infants with PVL documented by MRI.[48]

IMPAIRMENT OF BRAIN GROWTH AND LONG-TERM DEVELOPMENT

Periventricular white matter injury has been strongly associated with long-term neurodevelopmental deficits in preterm infants.[81,87,88] The significance of abnormalities in myelination in relation to functional (neurologic) development has been extensively studied. Correlation was found between neurodevelopmental delay and delay in myelination.[25,36,96,111]

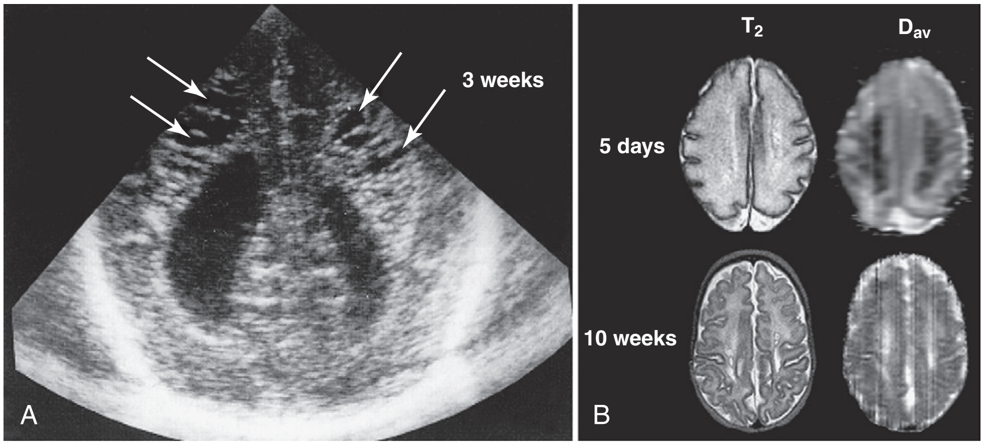

Figure 40–45. Ultrasound scan (**A**) of bilateral cystic periventricular leukomalacia *(arrows)*. **B**, The evolution of the lesions identified on DWI (D_{av}) at 5 days of age with the development of cystic lesions on T2-weighted MRI and apparent diffusion coefficient map (D_{av}) at 10 weeks of age. *(In part from Inder T, et al: Early detection of periventricular leukomalacia by diffusion-weighted magnetic resonance imaging techniques,* J Pediatr *134:631 1999.)*

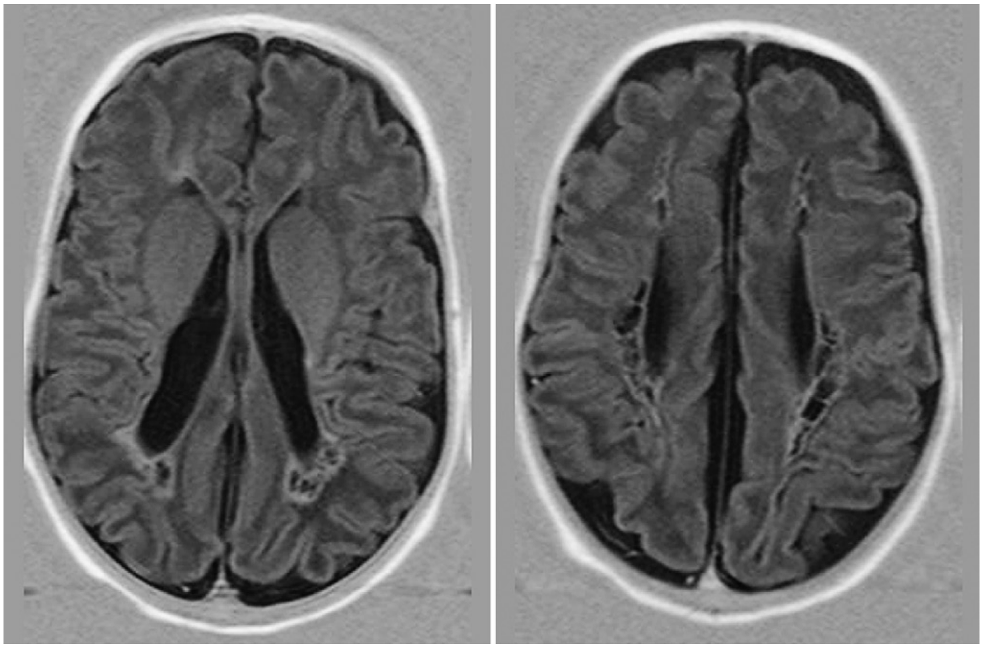

Figure 40–46. Axial inversion recovery MR images with T1-weighted contrast illustrating chronic phase of periventricular leukomalacia with multiple bilateral cystic lesions with high signal gliotic scars and calcifications in the periphery of the cystic lesions. Note the loss of white matter volume with cerebral atrophy.

The major long-term morbidity of the focal component of periventricular leukomalacia is spastic diplegia. This motor disturbance has as its central feature a spastic paresis of the extremities with greater effect on lower than upper limbs. More severe lesions with lateral and posterior extension into the centrum semiovale and corona radiata are associated with effects on the upper extremities or visual and cognitive deficits.

The development of three-dimensional MRI methods combined with image postprocessing techniques has allowed volumetric assessment of brain development and an absolute quantitation of myelination.[17,45] These techniques allow exact definition of brain volume and can, therefore, accurately monitor brain growth and measure cerebrospinal fluid volume and changes in cortical gray matter volume. Three-dimensional MRI volumetric techniques were used to evaluate the effect on subsequent brain development of early white matter injury in premature infants. Three groups of infants were studied at 40 weeks' postconceptional age: premature infants with preceding evidence for periventricular white matter injury by cranial ultrasound and MRI; premature infants who had no prior evidence of white matter injury; and control term infants (Fig. 40-48).

In premature infants with preceding white matter injury, the volume of myelinated white matter at term was significantly lower than in premature infants without prior white

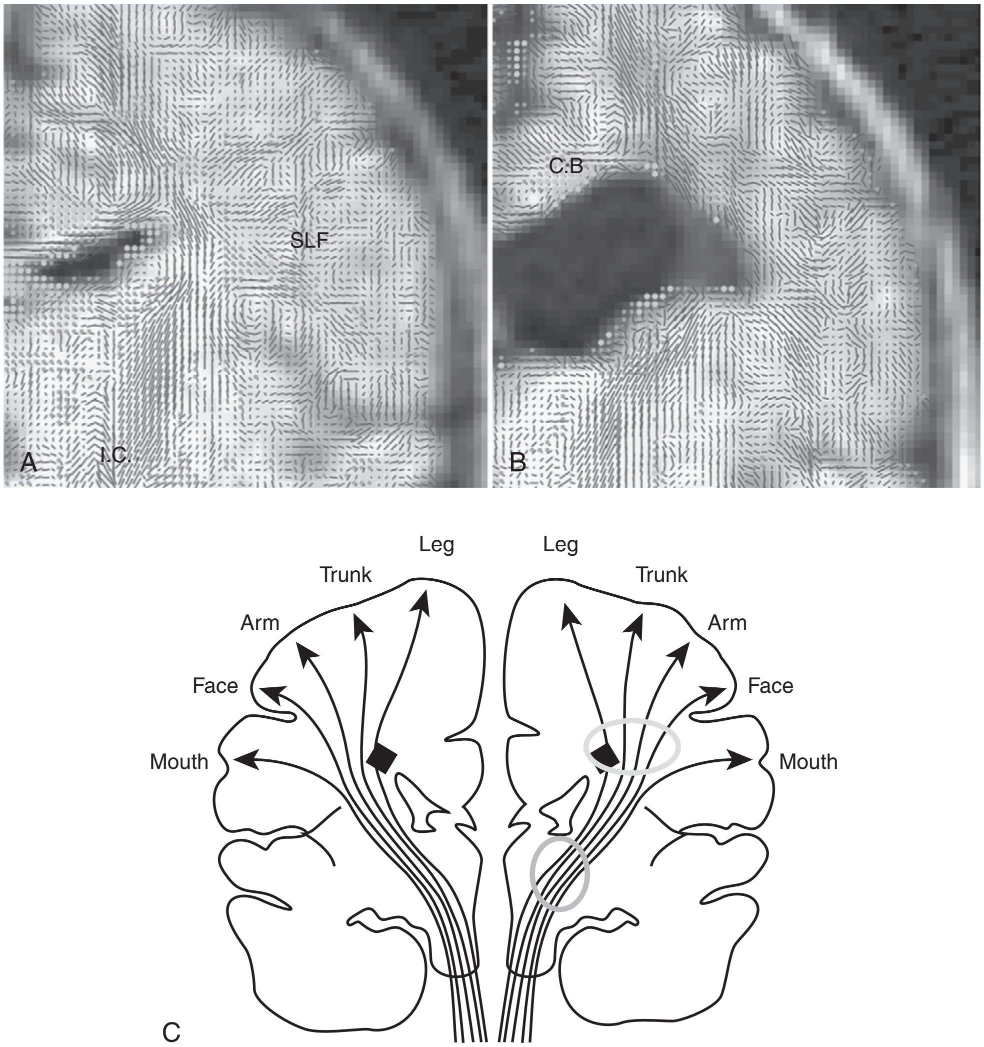

Figure 40–47. See color insert. Diffusion vector maps overlaid on coronal diffusion-weighted images for a premature infant at term with no white matter injury (**A**) and a premature infant at term with perinatal white matter injury (**B**). The posterior limb of the internal capsule (I.C.) in **A** shows more homologous directed vectors that are longer and more densely packed than in the internal capsule of **B.** Anteroposterior-oriented white matter fibers in the area of the superior longitudinal fasciculus (SLF; yellow and green dots with yellow representing higher anisotropy than green) in **A** indicate the presence of fiber bundles that are missing or are less prominent in **B.** The only discrete anteroposterior fiber bundles that definitely are present in **B** are the cingulate bundles (C.B.). Fibers of the corona radiata appear less well organized in **B** than **A**. Loss of axons in the central white matter *(yellow area)* and the posterior limb *(red area)* will result in neuromotor disturbances illustrated schematically in **C**. (**A**, **B**, *From Hüppi P, Murphy B, Maier S, et al: Microstructural brain development after perinatal cerebral white matter injury assessed by diffusion tensor magnetic resonance imaging,* Pediatrics *107:455, 2001.)* **C**, *Schema reproduced from Volpe JJ:* Neurology of the newborn, *4th ed, Philadelphia, 2001, Saunders, p 362.)*

matter injury and infants born at term, providing a measure of the degree of delay of myelination. Furthermore, this study showed a marked decrease in cortical gray matter volume in preterm infants with prior periventricular white matter injury indicating impaired cerebral cortical development after early white matter injury. This finding may explain the intellectual deficits associated with periventricular leukomalacia in preterm infants.[51] Assessing moderately preterm infants without signs of white matter injury revealed cortical development similar to that of full-term infants.[116] Regional assessment of white matter myelination in preterm infants further revealed particular delay in myelination in the central and posterior part of the brain.[73] When assessing cerebellar volume at term there was a significant reduction of cerebellar volume of preterm infants when compared to term infants.[58] Unilateral cerebral white matter lesions resulted in contralateral

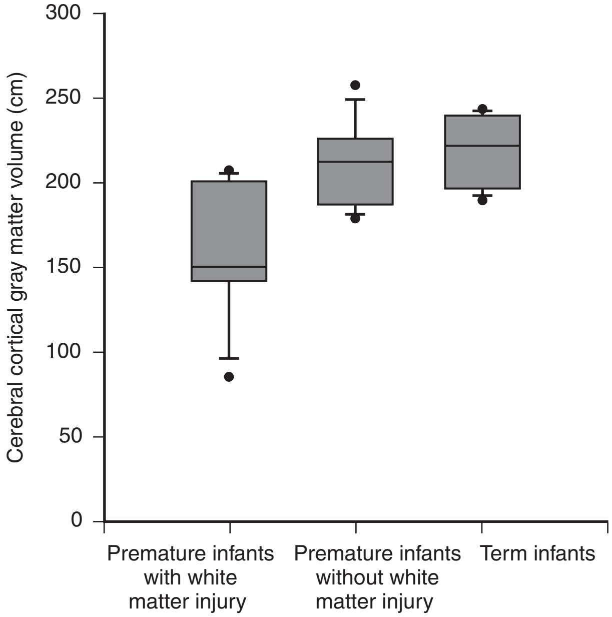

Figure 40–48. Figure illustrating the effects of perinatal white matter injury on subsequent cortical gray matter development at term with a significantly lower cortical gray matter volume determined by three-dimensional MRI with postacquisition image analysis in a group of preterm infants with perinatal white matter injury compared with control preterm and full-term infants. *(From Inder T, et al: The postmigrational development of polymicrogyria documented by magnetic resonance imaging from 31 weeks' postconceptional age,* Ann Neurol *46:755, 1999, with permission.)*

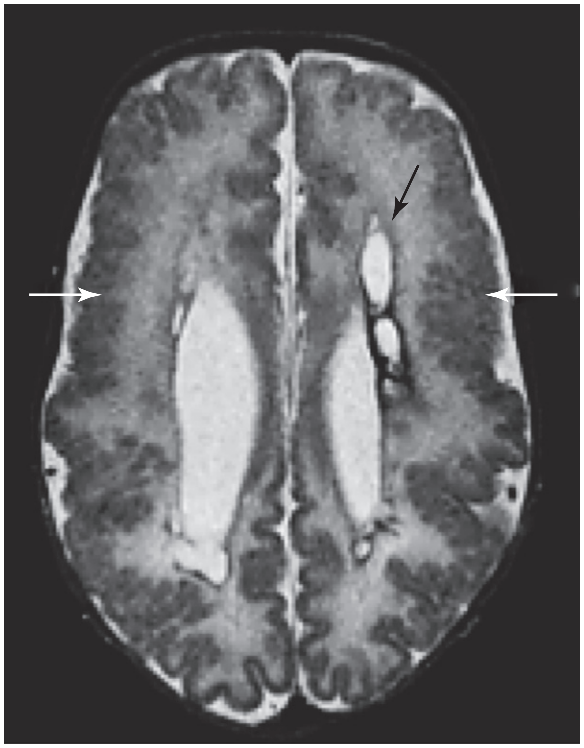

Figure 40–49. Axial T2-weighted MRI in a preterm infant of 25 weeks' gestational age at birth imaged at 31 weeks' gestational age showing cystic lesions in the periventricular white matter *(black arrow)* associated with bilateral polymicrogyria *(white arrows)*. *(From Inder T, et al: The postmigrational development of polymicrogyria documented by magnetic resonance imaging from 31 weeks' postconceptional age,* Ann Neurol *45:798, 1999, with permission.)*

reduction of cerebellar volume indicating a trophic interplay from cerebrocerebellar connectivity.[59]

Long-term follow-up studies of preterm infants have confirmed the permanent character of these disruptive/adaptive changes in brain development. Evaluations of 8-year-old preterm infants with volumetric brain assessment showed persistence of cortical gray matter reduction in preterm infants accompanied by a reduction in the volume of hippocampus, which correlated with cognitive scores indicating long-term functional consequences. Both cortical volume and cortical thickness were shown to be reduced in 15-year-old adolescents born prematurely.[68] Studying a larger cohort of preterm subjects at the same age, Nosarti and colleagues[80] noted widespread alterations in both gray and white matter volumes throughout the brain. Of note, volumes of several gray matter regions, including the middle temporal gyrus, superior temporal gyrus and sensorimotor region, and precentral and postcentral gyri were linearly related to gestational age for the preterm group. Furthermore, decreases in both gray and white matter volumes in the middle temporal gyrus were associated with cognitive impairment in the preterm group.

Human brain development is characterized by several interrelated steps. Neuronal and radial glial proliferation and migration are early events in brain development that are followed by a series of organizational events that result in the complex circuitry of axons and dendrites characteristic of the human brain. Elaboration of dendritic and axonal ramifications and attainment of proper alignment and orientation is most likely one of the driving forces for the folding of the cerebral cortex during development.[105] Such primary cortical folding may be influenced by preterm birth and intrauterine growth restriction. Infants with early white matter lesions have shown a trend toward increased sulcation in the overlying cortex. Early alteration of white matter connectivity, ensuing disruption to the white matter circuits and to the subcortical plate may, therefore, alter subsequent density, survival, and organization of cortical neurons. In severe cases, secondary polymicrogyria after primarily early white matter injury has been described (Fig. 40-49).[50] Neuropathologic study of cerebral cortex in preterm infants has revealed cortical dysplasia in areas overlying destroyed white matter.[66] These abnormalities of cortical development may be found secondary to disturbances of afferent input to and efferent output from areas of the cortex, as caused by disruption of the respective white matter axons.[66] Cortical volume changes in three-dimensional MRI[51] as described earlier are probably representative of these cortical alterations and may explain the increased risk of cognitive impairment and epilepsy in infants with classic motor deficits (spastic diplegia) after injury to the immature white matter.

Intracranial Hemorrhage

Even though white matter damage is now considered to be the main determinant of cerebral palsy later in infancy, germinal matrix hemorrhage-intraventricular hemorrhage (GMH-IVH) is still a serious condition in premature infants, associated with a high mortality rate. Large IVHs, complicated by posthemorrhagic ventricular dilation or associated with a unilateral parenchymal hemorrhage, are associated with an increased risk of adverse neurologic sequelae. The widespread use of cranial ultrasonography since the early 1980s has shown a gradual decrease in incidence of IVH and has helped with the identification of risk factors. The increased use of magnetic resonance imaging (MRI) has helped to better define the site and extent of the lesion and to visualize associated white matter damage.

INCIDENCE

GMH-IVH mainly occurs in premature infants, and the risk is higher with decreasing maturity.[143] A 2003 study, however, also showed that an IVH, sometimes associated with a thalamic hemorrhage, can be seen in full-term infants, and this can be associated with a sinovenous thrombosis.[162]

The first studies, using computed tomography (CT) and ultrasonography, were performed between 1978 and 1983 and showed an incidence of 40% to 50% in infants with a birthweight of less than 1500 g.[15] In the 1990s, many groups noted a decline in the incidence to approximately 20% of infants with very low birthweight,[8,65] but this decline has not been confirmed by others,[6] and no further decline was noted in a cohort of the Vermont Oxford Network.[67] Since the early 1980s, the incidence of intraparenchymal hemorrhage has also shown a decline, although this decline was not found in all studies.[76] The average incidence for intraparenchymal hemorrhage is now 5% to 11%.[8,30,32,76] An even lower incidence of 3% was reported in a French population-based cohort.[74] The decrease in the incidence of GMH-IVH is mainly attributed to the increased use of antenatal corticosteroids and the postnatal use of surfactant.[44,65,124,130]

Timing of the Hemorrhage

Accurate timing of GMH-IVH is possible only when sequential ultrasonographic studies are performed. A diagnosis of a hemorrhage of antenatal onset can be made only when the first ultrasonogram is performed on admission, within a few hours after delivery.[79] Many studies have shown that almost all hemorrhages develop within the first week after birth, and many of them within the first 48 hours after birth. Progression of a GMH-IVH over 1 to 2 days is not uncommon, and this applies especially to an IVH progressing to an intraparenchymal hemorrhage.[30] Venous infarction is the most likely underlying mechanism for this progression (see Neuropathology later). Only approximately 10% of cases of GMH-IVH occur beyond the end of the first week, in contrast to periventricular leukomalacia, where late onset is not uncommon.[2] Lesions seen in the caudothalamic groove after several weeks are probably not hemorrhagic in origin and are better referred to as *germinolytic necrosis*.[127] They are more common in infants with chronic lung disease and can also be seen in infants with postnatally acquired cytomegalovirus infection.

NEUROPATHOLOGY

Ruckensteiner and Zollner[126] were the first to point out that GMH-IVH developed after hemorrhage in the subependymal germinal matrix, a structure that is most prominent between 24 and 34 weeks of gestation and has almost completely regressed by term. Germinal matrix tissue is abundant over the head and body of the caudate nucleus, but can also be found in the periventricular zone. More recently, MRI has confirmed just how extensive this tissue is in preterm infants. The germinal matrix contains neuroblasts and glioblasts that undergo mitotic activity before migrating to other parts of the cerebrum. Bleeding into the caudothalamic part of the germinal matrix was predominant in the large autopsy series from New Jersey, but more than a third of cases also had bleeding into the temporal or occipital germinal matrix outer zones.[110] The germinal matrix receives its blood supply from a branch of the anterior cerebral artery known as the Heubner artery. The rest of the blood supply is derived from the anterior choroidal artery and the terminal branches of the lateral striate arteries.[58] Vessels in the germinal matrix are primitive and cannot be classified as arterioles, venules, or capillaries and are often referred as the *immature vascular rete*. Venous drainage of the deep white matter occurs through a fan-shaped leash of short and long medullary veins through which blood flows into the germinal matrix and subsequently into the terminal vein, which is positioned below the germinal matrix.[140] The anatomic distribution of parenchymal lesions associated with GMH-IVH suggest venous infarction due to obstruction of this vein.[54]

Germinal Matrix Hemorrhage

Most GMHs arise in the region of the caudate nucleus. Although GMHs at the level of the caudate nucleus are identified with ultrasonography, MRI has shown that GMH also occurs in the germinal matrix in the roof of the temporal horn. The size of the GMH changes with the maturity of the infant: the less mature the infant, the larger the GMH. The site also varies with maturity, with occurrence over the body of the caudate nucleus in the less mature infant and over the head of the caudate nucleus in the more mature infant.[58] When the GMH is followed longitudinally with ultrasonography, a subependymal cyst is seen as a sequel after several weeks, and this cyst is often still present at term equivalent age.

Intraventricular Hemorrhage

Hemorrhages occurring in the germinal matrix often rupture through the ependyma into the lateral ventricle and are then referred to as an *IVH*. These hemorrhages can vary considerably in size and, if large, can lead to acute distention of the lateral ventricle. Large clots can be present, seen as casts at postmortem examination or with cranial ultrasonography, and these can sometimes change position with repositioning of the infant. The blood can fill part of or the entire ventricular system, spreading through the foramen of Monro, the third ventricle, the aqueduct of Sylvius, the fourth ventricle, and the foramina of Luschka and Magendie to collect eventually around the brainstem in the posterior fossa. Clot formation can lead to outflow obstruction at any level, but most commonly at the level of the aqueduct of Sylvius, or more diffusely at the level of the arachnoid villi. More gradual progressive ventricular dilation occurs especially in those with a large GMH-IVH; this is known as *posthemorrhagic ventricular dilation*. This can be transient or persistent. In a small group, it can be rapidly progressive and noncommunicating, usually because of obstruction at the level of the aqueduct of Sylvius or the outlet foramina of Luschka and Magendie. Unilateral outflow obstruction at the level of the foramen of Monro can lead to unilateral hydrocephalus (Fig. 40-50). In cases of communicating progressive posthemorrhagic ventricular dilation, the increase in ventricular size is more gradual and is considered to be caused by an obliterative arachnoiditis due to blood collecting in the subarachnoid spaces of the posterior fossa, leading to an imbalance between cerebrospinal fluid (CSF) production and reabsorption.

Parenchymal Hemorrhage

The most severe type of hemorrhage involves the parenchyma. This type of lesion occurs in approximately 3% to 15% of all hemorrhages.[74,76] A recent study made us aware of the different veins involved in this type of lesion.[35] Direct extension into the parenchyma from pressure of blood in the ventricle is now considered unlikely. Some still take the view that all parenchymal hemorrhages are originally ischemic in origin, with any bleeding being a secondary complication. However, most agree that a unilateral parenchymal lesion accompanying GMH-IVH is most often caused by the presence of the GMH leading to impaired venous drainage and venous infarction. Gould and colleagues[54] showed that the ependyma remained intact, indicating that there had not been an extension of the preceding IVH. These lesions almost invariably show a moderate to large IVH on the ipsilateral side. The parenchymal hemorrhage is mostly unilateral but can occur in both hemispheres. A score was recently introduced, taking into account whether the lesion is unilateral or bilateral, the presence of a midline shift, and the number of regions that are involved.[6] The appearance of the intraparenchymal hemorrhage has changed since the early 1990s. Instead of a unilateral globular hemorrhagic lesion, in continuity with the lateral ventricle and evolving into a single

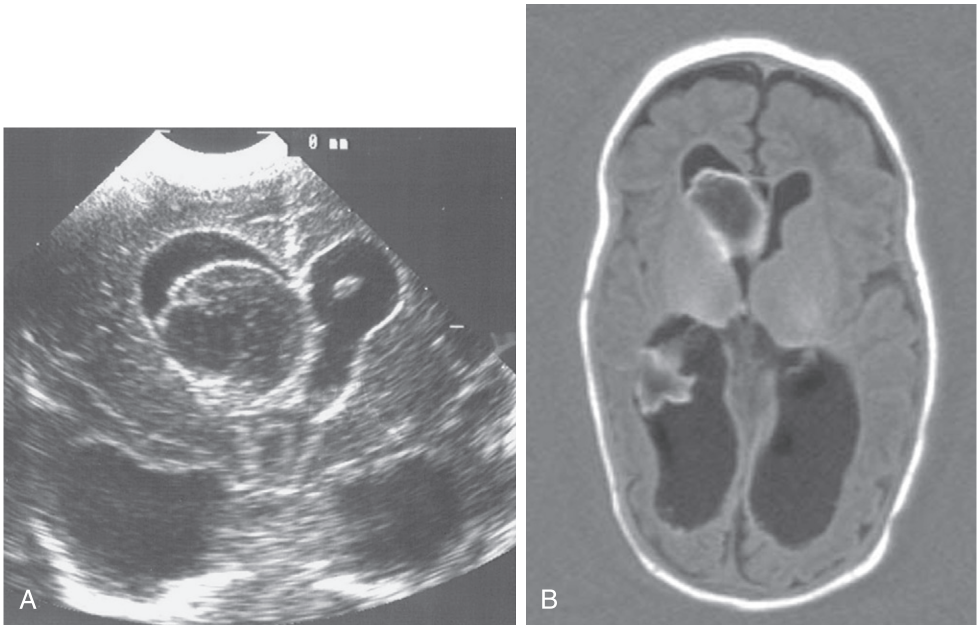

Figure 40–50. Cranial ultrasonography, coronal view, shows large right-sided intraventricular hemorrhage of antenatal onset in an infant born at term (**A**). The clot has started to resolve and has become less echogenic. The foramen of Monro appears to be (partially) occluded, leading to severe posthemorrhagic ventricular dilation, especially of the right ventricle. Magnetic resonance image, T1-weighted sequence, of this infant at 6 weeks after birth still shows the resolving intraventricular clot, irregular outline of the ventricular system, and bilateral absence of myelination of the posterior limb of the internal capsule (**B**).

porencephalic cyst, a smaller, triangular parenchymal lesion can be seen, with the tip of the triangle toward the lateral ventricle. There may be partial or even no communication of the parenchymal hemorrhage with the lateral ventricle, and an evolution into a few cystic lesions, separate from or partially in communication with the lateral ventricle, can be seen after several weeks (Figs. 40-51 and 40-52).[30] This type of lesion is sometimes classified as *unilateral periventricular leukomalacia* (PVL), but in view of the later MRI appearance, with very focal instead of diffuse gliosis, this appears to be incorrect. It is possible that improvement in neonatal care is associated with the change in appearance seen over time.

Intracerebellar Hemorrhage

Cerebellar hemorrhage was always considered uncommon, but the increased use of routine MRI in preterm infants has shown that this condition is not as rare as previously thought.[97] Some suggest that this problem is especially common in very immature infants. The condition has been reported in 2.5% of high-risk preterm infants.[81,97] Ultrasonography performed through the posterolateral fontanelle is more successful in making the diagnosis, but is still inferior to MRI. Cerebellar atrophy without an apparent cerebellar hemorrhage has also been reported as a common sequel of severe immaturity.[12,98] Reduced cerebellar volumes were only shown on three-dimensional MRI in preterm infants at term equivalent age, in association with supratentorial pathology, such as hemorrhagic parenchymal infarction, IVH with dilation, and periventricular white matter damage.[136]

PATHOGENESIS

The precise nature and origin of GMH-IVH remain uncertain. Although some groups have suggested that the capillaries in the germinal matrix do not rupture easily, others have suggested that they can rupture because the vessels are immature in structure with little evidence of basement membrane protein and they are of relatively large diameter. Early neuropathologists considered subependymal bleeding to be entirely venous in origin. This theory was rebutted by the work of Hambleton and Wigglesworth[58] and Pape and Wigglesworth,[111] who suggested from their injection studies that capillary bleeding was more prominent than terminal vein rupture. There has been a return to the concept that most parenchymal hemorrhages are due to venous infarction[54,140] or to a reperfusion injury after an ischemic insult.[152] An anatomic analysis of the developing cerebral vasculature did not show precapillary arteriole-to-venous shunts.[3]

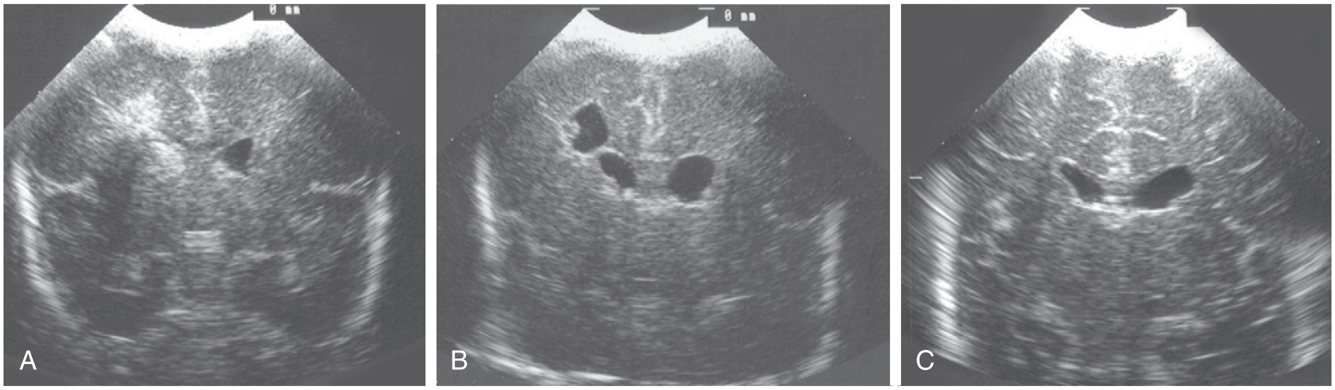

Figure 40–51. **A**, Cranial ultrasonography, coronal view, shows intraventricular hemorrhage and parenchymal hemorrhage not in communication with the lateral ventricle. **B**, Three weeks later, a single cystic lesion is present after resolution of the hemorrhage. **C**, At term, the cyst is no longer seen.

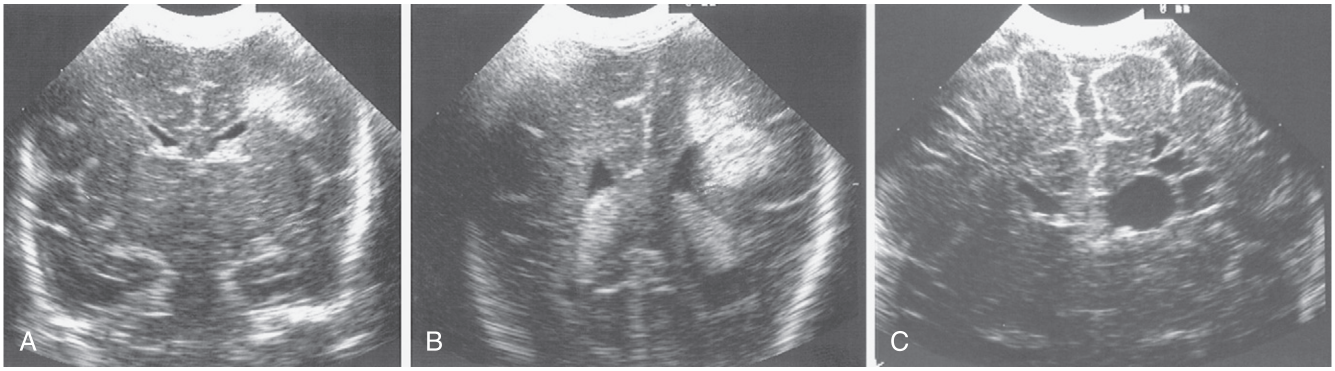

Figure 40–52. **A**, **B**, Cranial ultrasonography, coronal view, shows intraventricular hemorrhage and parenchymal hemorrhage not in communication with the lateral ventricle. **C**, At term age, multiple cysts are seen adjacent to the lateral ventricle.

Prenatal Factors

Histologic signs of amniotic infection have been shown to increase the risk of GMH-IVH.[141] This fits in well with acute inflammatory placental lesions[149] and increased serum levels of interleukin (IL)-1β, IL-6, and IL-8, noted to be associated with severe IVH in extremely premature infants.[62,141,164] In one of these studies, a correlation was shown between blood cytokine concentrations and altered hemodynamic function.[164] Cord blood IL-6 concentration correlated inversely with newborn systolic, mean, and diastolic blood pressures. The number of infants with an IVH was limited, but in the five infants with an IVH, the placenta significantly more often showed evidence of fetal inflammation.[164] An increase in total leukocytes during the first 72 hours after birth,[114] as well as an increased ratio of immature to total white blood cells, was also recognized as independent risk factors for GMH-IVH.[164]

Maternal preeclampsia has been associated with a reduced risk of GMH-IVH.[27,130] The protective effect appears to be due to enhanced in utero maturation of the fetus. Administration of antenatal corticosteroids is, according to several studies, the most important protective factor against development of GMH-IVH.[130] The effect may be due to a direct maturational effect on the brain, but other factors may also be involved, like the reduction of the severity of lung disease and the decreased need for inotropes. One study did not find a protective effect of antenatal corticosteroid administration.[114]

Intrapartum Factors

Whether the mode of delivery plays a role is still uncertain.[59,90] A reduced mortality but not a reduced risk of a GMH-IVH was recently reported in a Swedish population-based study for preterm infants with a gestation of 25 to 36 weeks.[64] In a cohort study, a protective effect of a cesarean section was seen only for the most immature infants (less than 27 weeks' gestation).[143]A vaginal breech delivery is in some studies associated with a higher risk of large GMH-IVH, but this effect was lost in a multivariate analysis.[130] Neonatal transport for infants born outside a tertiary center has also been shown to be a risk factor.[143] A decrease in the number of infants who need transportation will reduce the number of infants with GMH-IVH.

Delayed cord clamping was recently associated with a reduction in GMH-IVH as demonstrated by five infants (14%) in the delayed clamping group compared with 13 infants (36%) in the nondelayed group ($P = .03$).[94] The impact of delayed cord clamping on IVH was evaluated, adjusting for gestational age and cesarean section. The final model indicated that the IVH rate was more than three times higher in the immediate cord clamping group (OR 3.5, 95% confidence interval [CI] CI 1.1–11.1). In a systematic review, there were no significant differences for infant deaths, but a significant difference in the incidence of IVH was reported in 7 of the 10 published studies ($P = .002$).[119]

Neonatal Factors

Respiratory problems, particularly respiratory distress syndrome (RDS), have been recognized as important risk factors in the development of GMH-IVH. This association is most likely not causal but due to the associated complications occurring during mechanical ventilation for RDS, such as hypercarbia, pneumothorax, and acidosis. Because of improvement in ventilatory techniques, including an increased use of nasal continuous positive airway pressure, hypercarbia and severe acidosis have become less common. Hypercarbia, a potent cerebral vasodilator, was noted in the past to be associated with GMH-IVH, and Levene and colleagues showed a very high risk for an IVH when a combination of hypercarbia and severe acidosis was present.[78]

Cardiovascular Factors

The immature brain is considered vulnerable to fluctuations in blood pressure owing to limitations in autoregulation of cerebral bloodflow.[84] Impaired autoregulation renders the cerebral circulation "pressure-passive" and hence unprotected from any wide swings or changes in blood pressure. This applies especially to sick preterm infants. Data initially obtained using a radioactive xenon tracer[84] showed a direct linear relationship between blood pressure and cerebral bloodflow in a small number of infants. Similar findings were obtained using near-infrared spectroscopy.[145] Using these techniques, it was recently shown that routine caregiving procedures in critically ill preterm infants were associated with major circulatory fluctuations and that these cerebral hemodynamic changes were associated with early parenchymal ultrasound abnormalities.[83] Muscle paralysis was noted to stabilize the fluctuating bloodflow pattern and was followed by a reduction in GMH-IVH.[115] Looking at a selected population of ventilated infants with evidence of asynchronous respiratory efforts, a significant reduction in intraventricular hemorrhage (any grade and severe IVH) was found, using muscle paralysis.[15a] The fluctuating pattern may be exaggerated in hypovolemia.[118] Hypotension is common in infants with severe RDS, and in the presence of a pressure-passive cerebral circulation, may lead to hypoxia-ischemia of the germinal matrix. Several groups have shown that arterial hypotension precedes the development of GMH-IVH,[153] with the hemorrhage occurring during a period of reperfusion. This finding is supported by a continuous ultrasonography study, which showed occurrence of the hemorrhage during an increase in blood pressure after a period of lower blood pressure.[43,108] The researchers showed a low flow in the superior vena cava, detected during the first few hours of life preceding an IVH. The antenatal administration of steroids is associated with a reduction in the need for blood pressure support. Following a reduction in the severity of RDS, this effect on the blood pressure may be most protective for the development of a GMH-IVH.[101] Early administration of fresh frozen plasma does not reduce the incidence of GMH-IVH.[107] A reduction in GMH-IVH has been seen during an era of closer attention to blood pressure, gentle handling, synchronous ventilation, and less severe RDS because of antenatal steroid and postnatal surfactant therapy, rather than because of any specific drug used as prophylaxis.[155] Measurement of cardiac troponin (cTnT) and N-terminal-pro-B type natriuretic peptide (NTpBNP), both markers of cardiac function at 48 hours after birth, has shown that infants with a patent ductus arteriosus and IVH grades III or IV and/or death had significantly higher median cTnT/NTpBNP levels compared with infants with a patent ductus arteriosus without IVH grades III or IV and/or death and those with spontaneous patent ductus arteriosus closure.[36]

Genetic Factors

Thrombophilic disorders, including the factor V Leiden mutation, which renders factor V resistant to cleavage by activated protein C, and the prothrombin G20210A mutation, which was found to be associated with raised plasma concentrations of prothrombin, were suggested to play a role in the development of GMH-IVH. However, a large prospective study was unable to confirm previously reported associations of hemostasis gene variants and development of IVH in infants with very low birthweight.[61] Interleukin-6 CC genotype increased the risk of the development of severe hemorrhagic lesions (OR 3.5; 95% CI 1.0-12.2; $P = .038$).[60] This observation could, however, not be confirmed in a considerably larger sample size.[53] Antenatal porencephaly was recently reported to be associated with a mutation in the collagen 4A1 gene (*COL4A1*) encoding procollagen type 4α1, a basement membrane protein in two preterm siblings and preterm twins.[11a,34]

DIAGNOSIS

With ultrasonography largely available in neonatal units, most high-risk preterm infants have routine ultrasonographic examinations soon after admission or within the first few days after birth. Three clinical syndromes, however, can be recognized in preterm infants not paralyzed or heavily sedated on the ventilator.[152] The first is known as *catastrophic deterioration*, noted by a sudden deterioration in the infant's clinical state, such as an increase in oxygen or ventilatory requirement, a fall in blood pressure, or acidosis. More often, however, a drop in hematocrit is seen without a clear change in the infant's condition. The *saltatory syndrome* is more common and gradual in onset, presenting with a change in spontaneous general movements. The third and most frequent presentation is *asymptomatic*; 25% to 50% of infants with GMH-IVH have no obvious clinical signs.

A classification system suitable for describing early and late ultrasonographic appearances and based on that suggested by Volpe[152] is given in Table 40-5.

Ultrasonography is a noninvasive bedside technique, using the anterior fontanelle as an acoustic window. Good correlations of ultrasonographic GMH-IVH signs with autopsy findings have been reported. With the increased use of MRI, it has become apparent that GMHs at sites other than at the level of the caudate nucleus, like the roof of the temporal horn, are not always identified using ultrasonography. With ultrasonography, it also is not always possible to be certain about the presence or absence of a small associated IVH. Immediate access to ultrasonography in contrast to MRI, and the fact that the examination can be repeated as often as indicated, still makes this technique the first method of choice.[87]

Timing of the examination depends on the questions raised. An examination within hours after delivery helps in timing the lesion as antenatal or postnatal. When trying to determine risk factors, sequential scans until the GMH-IVH is diagnosed are also important. A single scan at the end of the first week shows 90% of all hemorrhages as well as their maximum extent. Further ultrasonographic examinations (up to two to three times weekly) are required in infants with any degree of hemorrhage to detect the occurrence of posthemorrhagic ventricular dilation, which occurs in approximately 30%, and the occurrence of associated PVL[77,103]; the more severe the hemorrhage, the higher the risk for development of post-hemorrhagic ventricular dilation. Posthemorrhagic ventricular dilation tends to develop 10 to 20 days after the onset of GMH-IVH.

Experts from the American Academy of Neurology, the Child Neurology Society, and the American Academy of Pediatrics have published recommendations on the use of ultrasonography to evaluate premature neonates.[92] It is recommended that all neonates younger than 30 weeks' postmenstrual age be screened with cranial ultrasonography because 23% of this group have significant abnormalities detected. Optimal timing of the ultrasonography allows detection of clinically unsuspected IVH and evidence for PVL or ventriculomegaly. At a minimum, it is recommended that scans be performed at 7 to 14 days of age and at 36 to 40 weeks' postmenstrual age. Data do not support routine MRI for all neonates with abnormal results on screening ultrasonography.

Unilateral intraparenchymal hemorrhage associated with a bilateral or ipsilateral GMH-IVH is now considered to be due to impaired drainage of the veins in the periventricular white matter, resulting in venous infarction.[30,140] This type of lesion is classically triangular or fan-shaped, with the apex at the outer border of the lateral ventricle. In some cases the lesion is globular with the apex of the triangle at the midline and a smooth outer border. The globular type of lesion (usually unilateral) evolves over 2 to 3 weeks into a porencephalic cyst (Fig. 40-53), whereas those intraparenchymal hemorrhages that are clearly separate from the ventricle at the start often form multiple small cysts (see Fig. 40-53).[30]

TABLE 40–5 Grading System for Neonatal Intraventricular Hemorrhage*

Description	Generic Term
Grade I: Germinal matrix hemorrhage	GMH
Grade II: Intraventricular hemorrhage without ventricular dilation	GMH-IVH
Grade III: Intraventricular hemorrhage and with acute ventricular dilation (clot fills >50% of the ventricle)	GMH-IVH ventriculomegaly
Intraparenchymal lesion—describe size, location	Intraparenchymal hemorrhage

*This represents an evolution of the system described in Papile LA, et al: Incidence and evolution of the subependymal intraventricular hemorrhage: a study of infants with birth weights less than 1500 grams, *J Pediatr* 92:529, 1978.

GMH, germinal matrix hemorrhage; IVH, intraventricular hemorrhage.

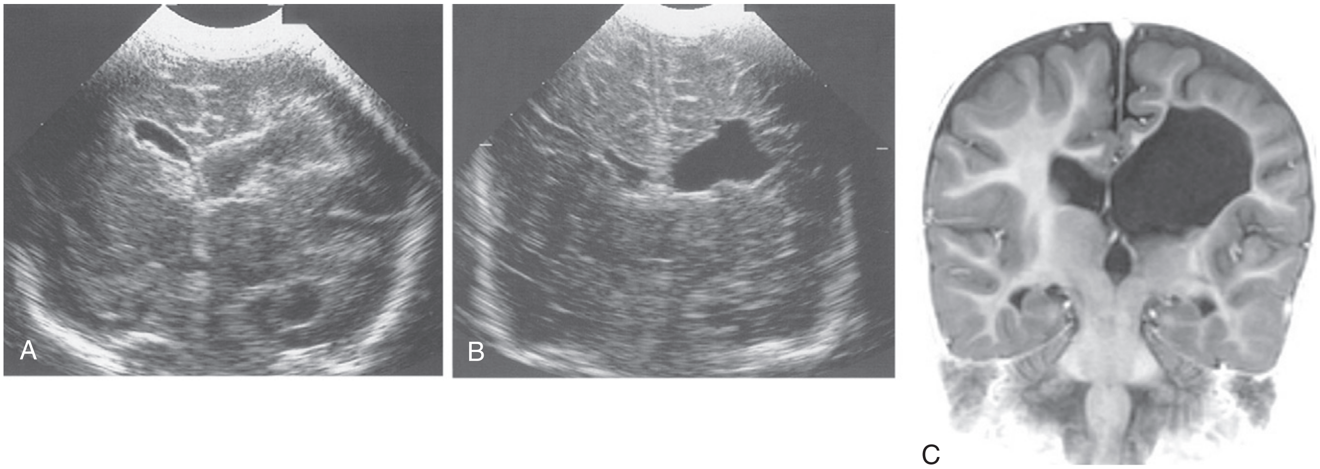

Figure 40–53. Cranial ultrasonography, coronal view, shows large intraventricular hemorrhage and parenchymal hemorrhage in communication with the lateral ventricle. **A**, The clot has started to resolve. **B**, At term age, a porencephalic cyst is present after resolution of the hemorrhage. **C**, Magnetic resonance image, T1-weighted sequence, of this infant at 18 months of age shows a large porencephalic cyst, loss of white matter, and reduced myelination on the affected side.

MANAGEMENT

Clinical management of children who have a GMH-IVH is not different from that of other at-risk preterm infants. Minimal handling, prevention of fluctuations in blood pressure or CO_2 levels, prevention of breathing against the ventilator, and optimization of any coagulopathy may be warranted in an attempt to prevent extension of the initial hemorrhage.[21] A blood transfusion may be needed in case of a large IVH associated with a drop in hemoglobin. Continuous electroencephalographic monitoring may be helpful in the detection of subclinical seizures (see Part 5 of this chapter). The use of fibrinolytic therapy in an attempt to resolve the initial clot has been disappointing and can even result in rebleeding.[157] Repeat ultrasonographic scans are indicated to diagnose posthemorrhagic ventricular dilation. Ventricular dilation seen on cranial ultrasonography usually precedes the development of clinical symptoms by several weeks. The clinical signs are a full fontanelle, diastasis of the sutures, and a rapid increase in head size. Sunsetting of the eyes is a late sign. Posthemorrhagic ventricular dilation is transient in approximately half of the infants and is persistent or rapidly progressive in the remaining cases.[103] Once it is recognized that the ventricles have begun to enlarge, the baseline size should be measured using ultrasonography. The most widely adopted measurement system is that of Levene and Starte.[77] This "ventricular index" is the distance between the midline and the lateral border of the ventricle measured in a coronal view in the plane of the third ventricle. Another useful measurement is the depth of the frontal horn taken just in front of the thalamic notch, with a height of more than 3 mm being used to define ventriculomegaly and one greater than 6 mm to suggest posthemorrhagic ventricular dilation.[22] Measuring the occipital horn in a sagittal plane can also be useful because there can be a discrepancy between the anterior and posterior horn width. Any measurement greater than 24 mm also suggests severe posthemorrhagic ventricular dilation (Fig. 40-54). Accurate measurement of the CSF pressure is required to make a distinction between infants with progressive hydrocephalus (i.e., those with raised intracranial pressure) and those in whom the dilation is due to cerebral atrophy (low pressure).[70] Raised CSF pressure can cause symptoms, including visual disturbance, seizures, feed intolerance, and apneas. In the long term, pressure-induced destruction of neuronal tissue can lead to motor handicap and mental retardation. Short-term adverse effects on the nervous system have been confirmed using somatosensory and visual evoked potentials, Doppler estimates of cerebral bloodflow velocity, and near-infrared spectroscopy. Soul and colleagues[133] showed a pronounced effect of CSF removal on cerebral perfusion, regardless of the opening pressure and the amount of fluid removed. The impact of removal of CSF on cerebral tissue was also assessed using advanced volumetric three-dimensional MRI, showing an increase in both cortical gray and myelinated white matter volume.[68] CSF hypoxanthine levels IL-8, IFN-γ and sFas (soluble Fas) were noted to be raised in infants with posthemorrhagic ventricular dilation and especially so in those with associated PVL.[10,39,132]

Even so, there is no direct evidence that early drainage of CSF alters the natural history or outcome of posthemorrhagic ventricular dilation. In two large, retrospective, observational studies, a significant reduction in the need for shunt placement was noted when intervention was started before the 97th percentile +4 mm line of the graph of Levene and Starte was crossed and when the threshold for inserting a subcutaneous reservoir was low.[14,31] The initial data of the drainage, irrigation, and fibrinolytic therapy (DRIFT) study showed a reduced need for shunt insertion, 22% compared with approximately 60% in other multicenter studies.[69,148,158] A subsequent randomized controlled trial was discontinued due to a high risk (33%) of rebleeding in the group allocated to DRIFT without an apparent positive effect on the need for a ventriculoperitoneal shunt.[159] A prospective international randomized study, randomizing for early or later placement of a subcutaneous reservoir, is now in progress.[14]

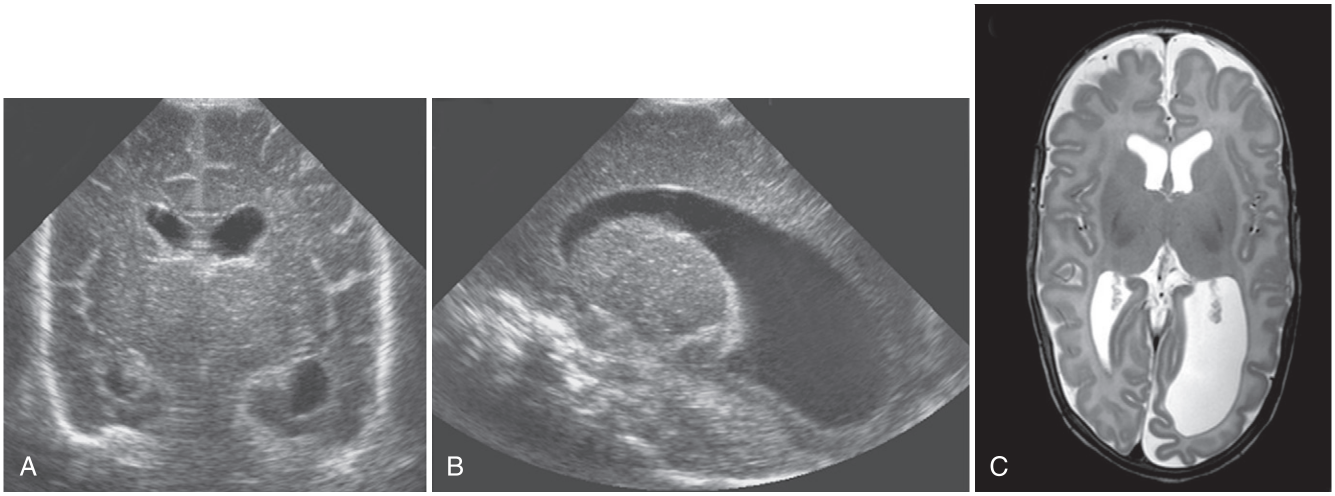

Figure 40–54. **A**, Cranial ultrasonography, coronal view, shows mild ventricular dilation. **B**, Parasagittal view obtained during the same examination shows severe dilation of the left occipital horn. **C**, The magnetic resonance image, T2-weighted, spin echo sequence still shows marked occipital dilation at term-equivalent age.

NEURODEVELOPMENTAL OUTCOME

Data about long-term neurologic and developmental outcome mainly deal with children who had a large IVH with or without parenchymal involvement. These follow-up data are still mainly based on neonatal ultrasonographic data. Associated PVL may have been missed using this technique, especially in children with posthemorrhagic ventricular dilation, in whom the periventricular white matter is more difficult to visualize. Children with small hemorrhages were until recently not considered to be at increased risk for development of a major handicap, even though they score lower on tests assessing visual-motor integration.[85,150] Recent three-dimensional volumetric imaging studies, however, have shown reduced gray matter volumes at term-equivalent age[113,146,147] associated with a reduced mental development index (MDI) on the Bayley Scale of Infant Motor Development (BSID)-II, but this was only significant in the most immature infants with gestation less than 30 weeks. The risk of poor outcome increases significantly with the presence of posthemorrhagic ventricular dilation (50%) and even further in those who require shunt insertion (75%).[117,148]

Children with ventriculomegaly present at term are at higher risk of a poor outcome.[91] In this study, ventriculomegaly was significantly more common after high-grade GMH-IVH and bronchopulmonary dysplasia. Outcome data for children with a unilateral parenchymal hemorrhage show a major neurodevelopmental disability in approximately 80%. The most common handicap is a hemiplegia contralateral to the side of the parenchymal hemorrhage. Ten infants with a porencephalic cyst following a parenchymal hemorrhage were followed into adolescence.[131] At all ages assessed, rates of motor, cognitive, and overall impairment were significantly higher compared with those in preterm control subjects ($P \leq .002$ for all tests). Six of the ten children were ambulatory when seen at 16-19 years required learning assistance in school, and had social challenges. In a retrospective hospital-based population study, outcome was considerably better than reported previously, with cerebral palsy occurring in only 7.4% of the infants with a large IVH (grade III) compared with 37 (48.7%) of the 76 infants with a parenchymal hemorrhage ($P < .001$).[14] Whether this better neurodevelopmental outcome was related to earlier treatment of posthemorrhagic ventricular dilation or due to a cohort with more localized lesions and of more mature preterm infants needs to be established, and a prospective randomized controlled trial is now underway.[14]

The data[14] are very much in contrast to those of a recent study looking at a large group of infants with a grade III-IV hemorrhage with and without a shunt.[1] Of the 562 infants with a grade III hemorrhage, 103 (18%) needed a ventriculoperitoneal (VP) shunt, compared with 125 of the 436 (29%) with a grade IV hemorrhage. Children with severe IVH and shunts had significantly lower scores on the BSID II compared with children with no IVH and children with IVH of the same grade and no shunt. An MDI less than 70 was found in 183 of 424 (43%) infants with a grade III hemorrhage without a shunt compared with 59 of 99 (60%) in those with a shunt. In those with a grade IV hemorrhage without a shunt, 143 of 295 (48%) had an MDI less than 70, compared with 87 of 115 (76%) of those requiring a shunt. Infants with shunts were at increased risk for cerebral palsy and head circumference at the less than 10th percentile at 18 months' adjusted age. Infants with a grade III hemorrhage without apparent associated white matter involvement are more likely to do well or may develop a diplegia, whereas those with a venous infarction are more at risk of developing a hemiplegia, depending on the site and extent of the lesion. A score introduced recently was helpful in predicting outcome.[7] Early prediction of development of a hemiplegia is now possible using MRI at 40 to 42 weeks. At term, myelination of the posterior limb of the internal capsule should be present (Fig. 40-55). In infants in whom hemiplegia subsequently developed, asymmetry and even lack of myelination of the posterior limb of the internal capsule were noted (Fig. 40-56).[29] Using diffusion tensor MRI, visualization of

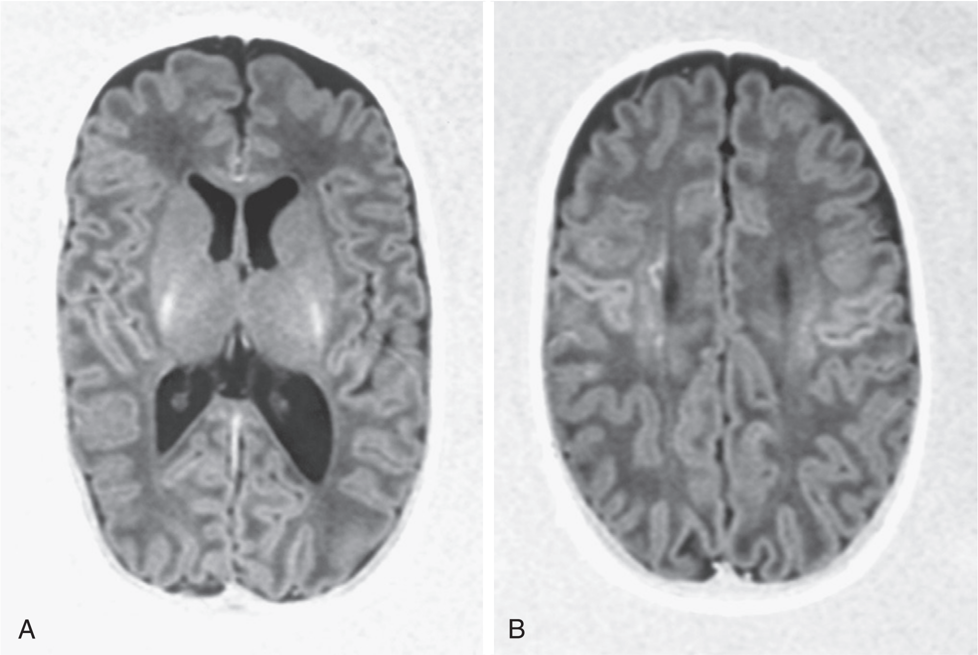

Figure 40–55. **A**, Magnetic resonance image, T1-weighted sequence, at term age, in same infant as in Figure 40-51. A symmetric high signal at the level of the posterior limb of the internal capsule is seen. **B**, At a higher level, a small triangular area of high signal intensity is still seen as a sequel of the parenchymal hemorrhage.

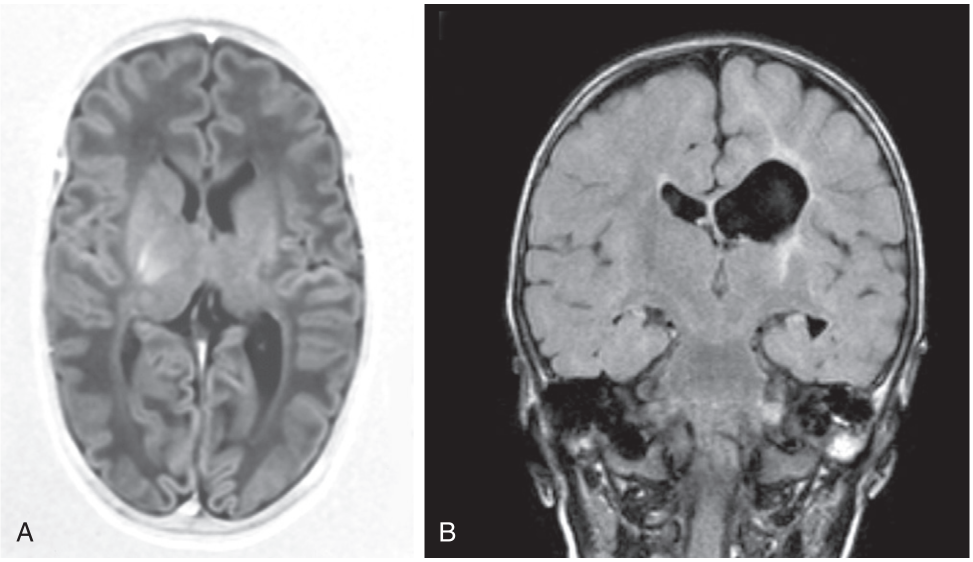

Figure 40–56. Magnetic resonance image, T1-weighted sequence, at term age, in same infant as in Figure 40-52. **A**, There is no symmetric high signal at the level of the posterior limb of the internal capsule **B**, A FLAIR sequence at 18 months of age shows high signal intensity suggestive of gliosis adjacent to the porencephalic cyst and across the internal capsule.

the tracts is possible at an earlier stage, but data are only available in preterm infants with a unilateral intraparenchymal hemorrhage examined later in infancy.[15b]

Outcome data of preterm infants with a cerebellar hemorrhage were recently reported and are reason for concern.[82] Neurologic abnormalities were present in 66% of infants with an isolated cerebellar hemorrhage compared with 5% of the control group. Infants with isolated cerebellar hemorrhagic injury versus controls had significantly lower mean scores on all tested measures performed at a median age of 32 months, including severe motor disabilities (48% versus 0%), expressive language (42% versus 0%), delayed receptive language (37% versus 0%), and cognitive deficits (40% versus 0%). The researchers concluded that cerebellar hemorrhagic injury in preterm infants is associated with a high prevalence of long-term pervasive neurodevelopmental disabilities. In a few other smaller studies of prematurely born children with cerebral palsy, involvement of the cerebellum was not uncommonly seen on MRI and these children showed a distinct clinical type of cerebral palsy with clinical features, including striking motor impairment and variable degrees of ataxia and athetosis or dystonia. Most were severely damaged, with cognitive, language, and motor delays, and all but one were microcephalic.[12,98]

PREVENTION

Both prenatal and postnatal pharmacologic prophylaxis have been used to reduce the incidence of GMH-IVH. With improvement in general neonatal care, a reduction has also been reported in many large neonatal units without the use of any drugs. Neonatal intensive care unit (NICU) characteristics were shown to affect the incidence of severe GMH-IVH, with NICUs with high patient volume and high neonatologist-to-staff ratio having a lower rate of severe GMH-IVH.[139]

The most promising specific prophylactic drugs are antenatal steroids.[44,130] A systematic review published in 2007 involving more than 4000 babies showed a significant reduction in the risk for GMH-IVH diagnosed by ultrasonography (OR 0.54; 95% CI 0.43-0.69). There was also a strong trend toward improved long-term neurologic outcome (OR 0.64; 95% CI 0.14-2.98).[124] It is not certain whether the effect is mainly due to increased lung maturation and therefore less severe RDS, stabilization of postnatal blood pressure, or perhaps a direct protective effect on the brain. It is not recommended that courses of antenatal corticosteroids be repeated because there may be a negative effect on brain growth.[18,100] Betamethasone instead of dexamethasone is recommended because dexamethasone has been associated with an increased incidence of PVL.[9]

Antenatal phenobarbital was shown to be protective in some but not all studies. The quality of some of these studies was not good because of lack of randomization or a placebo group. When these studies were excluded from a systematic review, no protective effect could be shown.[20]

Studies of antenatal administration of magnesium sulfate yield different results. No reduction in the incidence of either a small or a large GMH-IVH was found in a large, randomized, multicenter study.[17] Long-term follow-up, however, did show an improvement in gross motor function, but no significant reduction in development of cerebral palsy. In a recent multicenter randomized controlled trial, no significant reduction was found for the incidence of a large GMH-IVH (2.1% versus 3.2 %; relative risk [RR] 0.64; 95% CI 0.38-1.06). Moderate or severe cerebral palsy occurred significantly less frequently in the magnesium sulfate group compared to the control group (1.9% vs. 3.5%; RR 0.55; 95% CI 0.32-0.95).[125] Other tocolytic drugs have also been studied in relation to occurrence of GMH-IVH. Ritodrine was noted to be associated with a significantly reduced risk for development of a grade III or IV GMH-IVH, in contrast to administration of indomethacin and magnesium sulfate.[154]

Maternal vitamin K administration was associated with a trend toward reduction in the overall rate of GMH-IVH (RR 0.82; 95% CI 0.67-1.00).[19]

Phenobarbital was the first drug used postnatally in the prevention of GMH-IVH. Although the first studies were promising, a meta-analysis of 10 trials was unable to show a reduction in the incidence or severity of GMH-IVH (RR 1.04; 95% CI 0.87-1.25).[160]

The most promising prophylactic drug administered postnatally is indomethacin. The results of a meta-analysis involving 19 trials and a total of 2872 infants showed a significant reduction in the incidence of grades III and IV hemorrhage (pooled RR 0.66 [0.53-0.82]).[41] The children of the original cohort, studied by Ment and colleagues,[89] were assessed at 8 years of age and no effect of indomethacin was seen on long-term outcome.[151] Analysis of the original cohort by gender, however, showed that indomethacin halved the incidence of IVH, eliminated parenchymal hemorrhage, and was associated with higher verbal scores at 3 to 8 years in boys.[93] Another large trial was also unable to show an improvement in survival without sensory impairment at 18 months, despite a reduction in incidence of severe GMH-IVH.[128] A meta-analysis of ibuprofen involving 15 studies did not show a reduction in the incidence of IVH.[104]

OTHER HEMORRHAGES

See also Chapter 28.

Subdural and subarachnoid hemorrhages are probably underdiagnosed because they are difficult to recognize using cranial ultrasonography. Clinical signs may be mild or absent. A significant subdural hemorrhage is most often related to birth trauma, but a small subdural was noted to be a common occurrence in an MRI study looking at 111 consecutive full-term infants.[156] Nine infants had a subdural hemorrhage, three following a normal vaginal delivery (6.1%), five following forceps assisted delivery after an attempted ventouse delivery (27.8%), and only one following traumatic ventouse delivery (7.7%). Underlying mechanisms can be a tear of the dura, occipital diastasis, or rupture of bridging veins. A tear of the dura can occur after a precipitous delivery or from use of instrumentation, both of which are not very common with preterm delivery. A dural tear results in extensive bleeding from the adjacent sinus. Occipital diastasis can occur during a vaginal breech delivery with excessive extension of the neck of the infant, although vaginal breech deliveries are not commonly performed as a consequence of results of multicenter, randomized studies.[66] Rupture of the bridging veins is the most common etiology of a subdural hemorrhage and may be seen in association with a subarachnoid hemorrhage. These children are usually born at term and present with a full fontanelle, lethargy, apneas, or seizures. In case of a severe hemorrhage, a midline shift may be seen and surgery needs to be considered. The diagnosis usually is made using CT or MRI (Fig. 40-57). Hydrocephalus can develop from outflow obstruction and temporary external drainage, sometimes followed by permanent drainage, may be needed. Secondary cerebral infarction has also been reported and has been related to prolonged arterial compression.[55]

A small subarachnoid hemorrhage is sometimes (7%) seen in preterm infants at postmortem examination and does not usually cause any symptoms.[110] Blood can leak into the subarachnoid space after an IVH, by flowing through the aqueduct into the fourth ventricle and subsequently through the foramina of Luschka and Magendie into the subarachnoid space. Once again, the diagnosis is hard to make using ultrasonography unless the lesion is large and causes compression of brain tissue. Hydrocephalus is less commonly seen than in children with a subdural hemorrhage.

Vascular Lesions

CEREBRAL ARTERY INFARCTION

Because of increased access to neonatal MRI, infarction of a major artery, or a branch arising from it, is better recognized. This condition is often referred to as *neonatal stroke* or *perinatal arterial stroke*.[120] Information about incidence is becoming available with the introduction of neonatal registries.[25,86] Newborn infants are susceptible to neonatal stroke because of

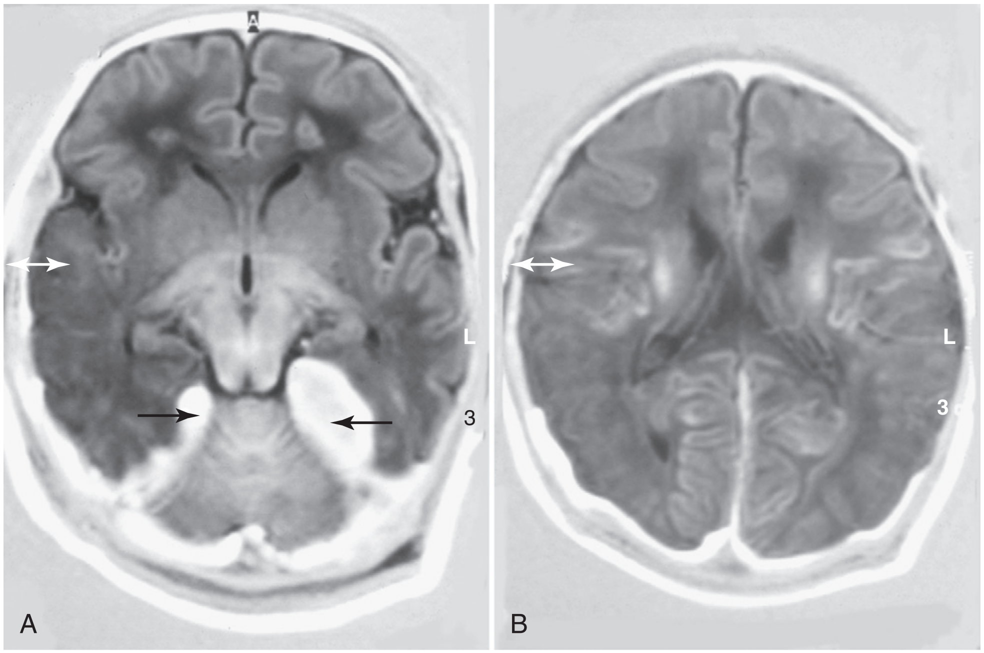

Figure 40–57. A, Magnetic resonance image, T1-weighted sequence, shows a large collection of blood in the posterior fossa with blood along the tentorium bilaterally *(black arrows)*. B, At a higher level, extensive cortical highlighting is seen posteriorly and in the region of the sylvian fissure (*white arrows*). A posterior trunk middle cerebral artery infarct is also seen on the right.

a number of factors present around the time of delivery, such as the hypercoagulable state of the mother, mechanical stress during delivery, the transient right-to-left intracardiac shunt, and the risk of dehydration during the first few days after delivery often associated with a high hematocrit and blood viscosity.[105] Neonatal stroke can be divided into sinovenous thrombosis and arterial ischemic stroke.[25] Both conditions still are not always detected because presenting symptoms may not always be clear and appropriate imaging is not always performed. Arteriovenous malformations are discussed in Chapter 45.

Sinovenous Thrombosis

An incidence of 41 per 100,000 newborn infants with sinovenous thrombosis was found in the Canadian Pediatric Ischemic Stroke Registry.[25] Most (66%) come to medical attention within 48 hours of birth, although infants can also develop symptoms 10 to 14 days after delivery, sometimes associated with dehydration or infection.[106] Almost half of the children (43%) with sinovenous thrombosis in this registry were newborns. Seizures are the most common presenting symptom and were reported in 70% of the infants from the Canadian Registry. Lethargy is also commonly present.[40,123] The fontanelle can be full and scalp veins may be prominent.

During the birth process, molding of the skull and overriding of the sutures of the different parts of the skull may occur and affect the underlying sinus, resulting in the occurrence of sinovenous thrombosis. Perinatal asphyxia is a commonly associated risk factor, seen in 24% of the newborns in the Canadian Registry. The superior sagittal sinus and the lateral sinuses are most commonly involved. Involvement of the straight sinus, the vein of Galen, and the internal cerebral vein has also been reported.[40] An associated IVH and especially a unilateral thalamic hemorrhage or periventricular congestion may help in clarifying the diagnosis.[70b,162] Wu and coworkers[162] noted that sinovenous thrombosis was significantly more common in full-term infants with an IVH and a unilateral thalamic hemorrhage (4 of 5) compared with newborns with an IVH only (5 of 21). They strongly recommend the diagnosis of sinovenous thrombosis be considered in any full-term neonate presenting with an IVH.

In another study by the same group, risk factors were analyzed in 30 full-term infants with a sinovenous thrombosis.[161] They reported that 29% of these newborn infants had been on extracorporeal membrane oxygenation and 23% had congenital heart disease. Only seven infants were tested for a genetic thrombophilia, and four of these seven were found to be positive.

A diagnosis can be made using Doppler flow ultrasonography, which may demonstrate absent or decreased flow in the affected sinus. Contrast-enhanced CT can also be used, showing the so-called empty delta sign, the lack of contrast filling. The best method is MRI and especially the use of magnetic resonance venography, which helps make a definitive diagnosis by showing a reduction or absence of venous flow in the affected venous sinus (Fig. 40-58).

There is no agreement about the use of antithrombotic therapy in this age group, but recommendations were recently made.[102] Different treatment policies were noted with physicians in the U.S. being less likely to treat neonates with CSVT with antithrombotic medications compared to physicians at non-U.S. centers, 25% versus 69% of neonates.[69a] The number of infants is limited, requiring many centers for performance of a randomized study.

More than 90% of newborns with sinovenous thrombosis survive, and 77% of survivors were considered to be normal at a mean follow-up of 2.1 years.[26,40] Data from the Canadian Registry are not so encouraging, with 61% of survivors having a neurologic deficit and 9% experiencing a recurrence of cerebral or systemic thrombosis.[25]

In the retrospective chart study by Fitzgerald and associates assessing 42 newborn infants, 57% presented with seizures and 60% had associated parenchymal infarcts, which

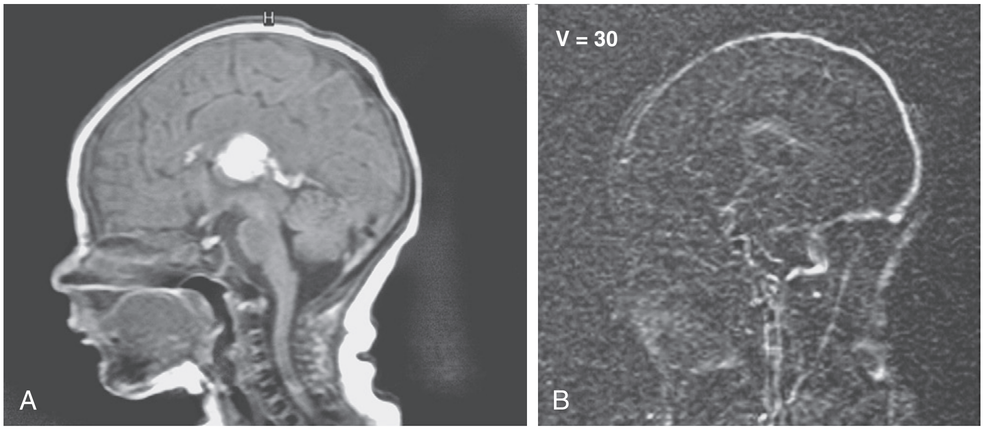

Figure 40–58. Magnetic resonance images obtained at 10 days' of age. T1-weighted sequence showed an area of high signal intensity compatible with hemorrhage in the thalamus. **A**, There is high signal at the level of the straight sinus. **B**, Magnetic resonance venography shows presence of flow in the superior sagittal sinus, but absence of signal at the level of the straight sinus.

were mainly hemorrhagic.[40] Seventy-nine percent had any form of impairment with 59% having cognitive impairment, 67% cerebral palsy, and 41% epilepsy. Infarction was associated with the presence of later impairment ($P = .03$).

Perinatal Arterial Ischemic Stroke

Cerebral infarction in the neonate has been defined as a severe disorganization or even complete disruption of both gray and white matter caused by embolic, thrombotic, or ischemic events.[5] In infants dying in the acute stage of the condition, the hemisphere is swollen and deeply congested. There is involvement of both white matter and cortex, with secondary hemorrhagic infarction in some cases. In infants who survive for longer, contraction of the affected area is seen with softening and multiple cystic degeneration, giving a honeycomb appearance on sectioning. A distinction between a unilateral parenchymal hemorrhage, which usually occurs in the preterm infant and evolves into a porencephalic cyst, and an infarct in the region of the middle cerebral artery, which usually occurs in a term newborn and evolves into an area of parenchymal cavitation, is recommended. A porencephalic cyst following a parenchymal hemorrhage of antenatal onset has, however, been referred to as *fetal stroke* and small porencephalic cysts following antenatal venous infarction have also been included within the spectrum of presumed perinatal stroke.[72,109]

Lesions involving the left hemisphere are three to four times more common than those of the right hemisphere. This may be due to hemodynamic differences early after birth related to the patent ductus arteriosus or a preferential flow across the left common carotid artery. Middle cerebral artery infarction occurs twice as often as involvement of any other artery.

Both de Vries and colleagues[28] and Mercuri and coworkers[95] used a classification system based on the main artery involved. Infarcts in the territory of the middle cerebral artery were further subdivided into main branch, cortical branch, and lenticulostriate branch infarction.

INCIDENCE

In the Canadian Registry, the incidence of perinatal arterial ischemic stroke was as high as 93 per 100,000 newborn infants, which is much higher than reported previously. Estan and Hope[37]studied a 7-year cohort and reported a prevalence of 0.025%, which is similar to the finding of Perlman and colleagues,[116] who found a prevalence of 0.02%. Several groups found neonatal stroke to be the second most common cause of neonatal seizures.[37,80] Data about focal infarction in preterm infants are scarce. In a recent hospital-based study we found an incidence of 7 per 1000 preterm infants with a gestational age less than 35 weeks.[11]

Convulsions are the most common presenting symptom.[71,135] They are usually of the focal clonic variety, but multifocal tonic or subtle seizures also may be seen (see also Part 5 of this chapter). Many of the infants show no major clinical neurologic abnormality between seizures. The largest population reported to date showed that 77% of the 215 infants presented with seizures, which were focal in almost all. Thirteen percent were admitted because of apneas, and 10% showed only hypotonia as a presenting symptom.[73] Symptoms can also be very subtle, especially in the preterm infant,[11,28] and the diagnosis can be easily missed. Presentation with a hand preference later in infancy may lead to a diagnosis, with an area of cavitation on CT or MRI, suggestive of a perinatal or in utero arterial ischemic stroke, which is now referred to as *presumed perinatal stroke*.[72,75]

DIAGNOSIS

After presentation with focal seizures in a child without an obvious history of perinatal asphyxia, care should be taken not to miss the diagnosis of arterial ischemic stroke. The middle cerebral artery is most commonly involved, and the infarct occurs more often on the left than the right side. Arterial infarcts of the anterior and posterior cerebral artery are less often diagnosed, possibly because of the lack of clinical symptoms in the neonatal period (Fig. 40-59). Involvement of the smaller branches of the middle cerebral artery is more often seen in preterm infants, whereas obstruction of the main branch is less common in this age group.[11,28] Infarcts can be hemorrhagic in 20%, and bilateral infarcts can be seen in 10% to 15% (Fig. 40-60).

In the absence of abnormalities on ultrasonography, MRI is recommended to confirm or exclude the diagnosis. Ultrasonography has not been considered reliable in making a diagnosis; this applies especially when the examination is made soon after the clinical presentation.[47] By the end of the first week, a wedge-shaped area of echogenicity, often with a linear demarcation line, restricted to the territory of

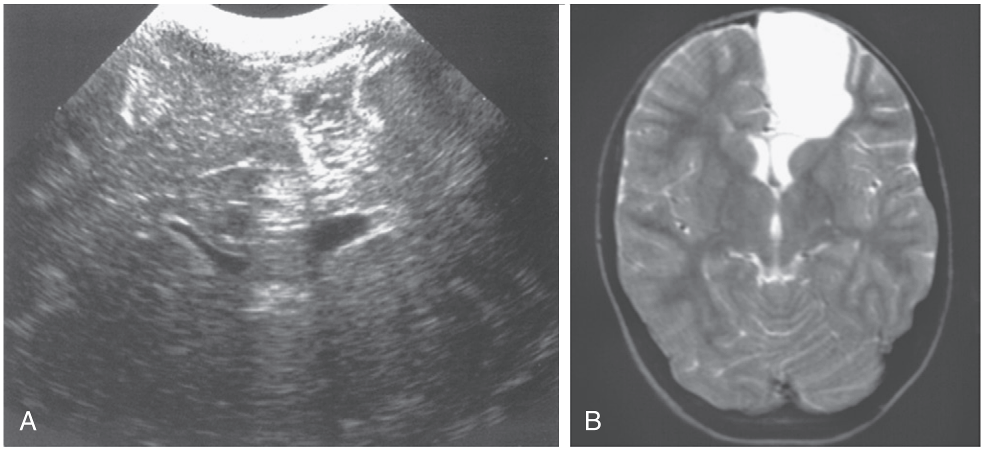

Figure 40–59. Preterm infant, gestational age 32 weeks. **A**, Routine ultrasonographic scan at 2 weeks showed an area of cystic evolution in the region of the left anterior cerebral artery. Mild ex vacuo dilation of the left ventricle is also present. **B**, T2-weighted magnetic resonance image, spin-echo sequence, at 7 years of age shows the parenchymal cavity in the same distribution.

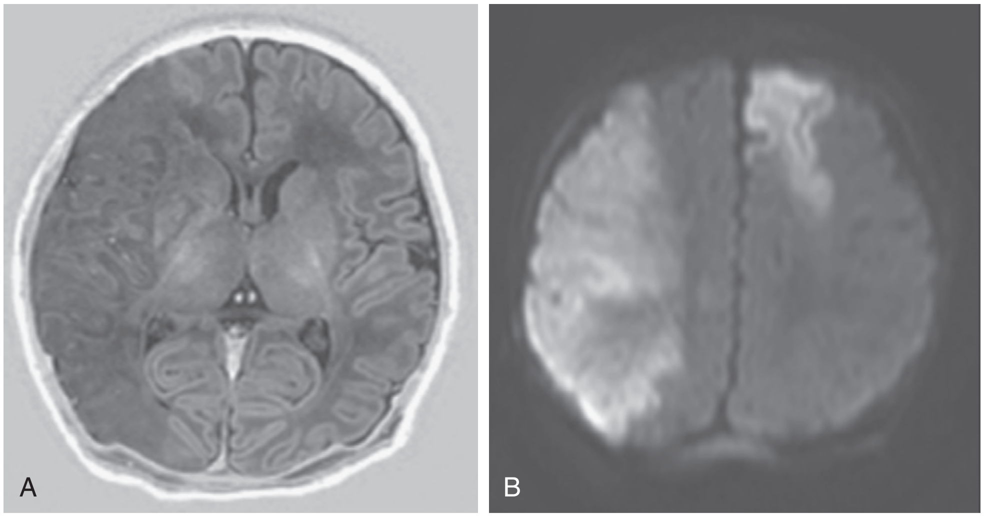

Figure 40–60. Full-term infant, magnetic resonance images obtained at 4 days of age. **A**, T1-weighted sequence shows low signal intensity in the distribution of the right middle cerebral artery suggestive of main branch involvement. **B**, Diffusion-weighted image shows high signal intensity in the same area, as well as a smaller area of high signal intensity in the distribution of the left anterior cerebral artery.

one of the main arteries, usually becomes apparent.[16] Cystic evolution can take place over the next 4 to 6 weeks, often associated with ex vacuo dilation of the ipsilateral lateral ventricle. Doppler ultrasonography can show asymmetry of arterial pulsations. Perlman and associates[116] noted decreased pulsations on the affected side, whereas Taylor[142] noted an increase in size and number of visible vessels in the periphery of the infarct and increased mean bloodflow velocity in vessels supplying or draining the infarcted areas in four of eight infants.

The threshold for performing MRI should be low in infants presenting with neonatal seizures. MRI plays an important role in making the diagnosis. If performed early after clinical presentation, diffusion-weighted MRI is very helpful. This technique shows abnormalities, indicating cytotoxic edema, at a very early stage, preceding abnormalities seen on conventional MRI. This technique also enables visualization of acute damage to the corticospinal tracts at the level of the midbrain.[33,71] Preliminary data suggest that these findings predict wallerian degeneration and development of subsequent hemiplegia.[33,71] A repeat scan can show asymmetry at the level of the mesencephalon, which can be seen as early as 6 weeks after onset of the infarction.[13] Magnetic resonance angiography, which allows investigation of the main vascular bed, can be used and can sometimes show dissection or occlusion of one of the main vessels. This may be rare, however, and this technique may also fail to show small vessel occlusion. Early assessment of structure-function relationship is possible using functional MRI. This technique was shown to provide additional information in a child with a posterior cerebral artery infarct.[129]

Reorganization of the somatosensory cortex can be followed using a combination of transcranial magnetic stimulation (TMS) and functional MRI.[38,129,137,138] Staudt and colleagues[138] showed that when a lesion abolishes the normal contralateral corticospinal control over the paretic hand, the contralesional hemisphere develops (or maintains) fast-conducting ipsilateral corticospinal pathways to the paretic hand. This reorganization with ipsilateral corticospinal tracts can mediate a useful hand function. Normal hand function, however, seemed only possible with preserved crossed corticospinal projections from the contralateral hemisphere. Guzzetta and colleagues also recently suggested that ipsilesional reorganization is more effective in the restoration of a good motor function as opposed to the contralesional reorganization.[57]

RISK FACTORS

Perinatal complications have been reported in more than 50% of newborn infants with a perinatal stroke.[46,75] Stroke among infants admitted with neonatal encephalopathy is an uncommon observation.[121] Cardiac disease, extracorporeal membrane oxygenation, and portal vein thrombosis have all been reported as associated risk factors.[112] Stroke was especially common (31%) among infants with transposition of the great arteries and this was associated with balloon septostomy.[88,99] Maternal cocaine abuse has also been considered to cause stroke. In a study of 43 women who abused crack cocaine during pregnancy, 17% of their infants had evidence of cortical infarction, compared with only 2% of the matched control group.[63] Studies conducted since the late 1990s have illustrated the importance of extensive investigations for an underlying genetic prothrombotic disorder.[23,46,73] In particular, activated protein C resistance caused by factor V Leiden mutation is an increasingly common associated finding.[23,70a] Factor V Leiden mutation, prothrombin mutation, increased lipoprotein-α, methylenetetrahydrofolate reductase C677T (MTHFR), and congenital protein C and protein S deficiency have also been reported as associated findings.[73] Population-based studies using case-matched controls found diverse etiologic factors responsible for perinatal arterial stroke in term infants. Infertility, preeclampsia, prolonged rupture of membranes, and chorioamnionitis have been identified as independent maternal risk factors.[26,75] A recurrence risk of 3% to 5% was given by both the Canadian and the German population-based studies.[73] A lower recurrence risk of 1.2 % was recently reported among 84 newborn infants with perinatal stroke.[42] Association with elevated maternal antiphospholipid antibodies (anticardiolipin antibodies, lupus anticoagulants) has also been reported (see also Chapter 18).[24] Data on risk factors in preterm infants are scarce.[11,51] Using case-matched controls (three controls per case, matched for gestational age), etiologic factors responsible for perinatal arterial stroke in preterm infants were recently studied and it was noted that these were different from those born at term. Twin-twin transfusion syndrome (19% versus 3%; OR 31.2; CI 2,9-340,0; $P = .005$), fetal heart rate abnormality (58% versus 26%; OR 5.2; CI 1.5-17.6; $P = .008$), and hypoglycemia (42% versus 18%; OR 3.9; CI 1.2-12.6; $P = .02$) were identified as independent risk factors for preterm stroke.[11]

PROGNOSIS

The outlook in most cases is relatively good. Published follow-up data from case reports suggest that the majority of the infants achieve independent walking before 13 months and more than half of all infants surviving neonatal stroke are entirely normal at 12 to 18 months of age.[48] Spastic hemiplegia is the most important sequela, particularly after infarction of the main branch of the middle cerebral artery. An increased incidence has been shown for male infants.[155] Two thirds of children with hemiplegia are of normal intelligence.[4,122] In a cohort studied by Mercuri and colleagues,[95] a hemiplegia developed in only 5 of 24 infants (20%). An additional two had mild asymmetry, and two had mild global delay. Hemiplegia or asymmetric tone tended to develop only in those cases with involvement of the hemisphere, basal ganglia, and internal capsule on first scan. When 22 of these 24 children were seen again at school age, 30% showed a hemiplegia and another 30% showed some neuromotor abnormality. Involvement of the internal capsule was always associated with some motor disturbance.[96] Deficits in higher-level cognitive skills may, however, become apparent during school, and this is more common in males.[155a] Homonymous hemianopia may follow posterior cerebral artery infarction.

Outcome data depend very much on the threshold for performing MRI, on the artery involved, and on whether the main branch is involved or only a cortical branch or one of the lenticulostriate branches. Mercuri and colleagues[95] found an abnormal background pattern, even when recorded on a two-channel electroencephalogram, to be the best early predictor of adverse neurologic outcome. Involvement of the internal capsule was also shown by this group to be a predictor of motor outcome.[96]

de Vries and coworkers[11,28] noted that involvement of the lenticulostriate branches was more common in preterm infants. Only 3 of 16 infants with involvement of a cortical branch or one or more lenticulostriate branches had cerebral palsy, in contrast to all five survivors with main branch involvement. Govaert and associates[56] suggested that cranial ultrasonography was important in the prediction of hemiplegia. In the parasagittal view, attention should be paid to involvement of the central groove, which is usually present in those with involvement of the main branch or the anterior trunk of the middle cerebral artery.

Seizures are a common complication and occur beyond the neonatal period in 25% to 67% of affected infants.[49] An infarct on prenatal ultrasonography ($P = .0065$) and a family history of epilepsy ($P = .0093$) were significantly associated with postneonatal epilepsy in the univariate analysis. As epilepsy may first develop later in childhood, the rate of epilepsy will be higher when follow-up is longer. Hippocampal tissue was examined in children in whom intractable epilepsy developed after a middle cerebral artery infarct. Hippocampal sclerosis was noted to be less common in those with early-onset stroke (before 28 weeks' gestation).[134]

Goodman[52] noted that half of all children with hemiplegia have psychiatric disorders (i.e., problems with behavior, emotions, or relationships interfering with the child's everyday life). They usually present with irritability, anxiety, and hyperactivity/inattention. This finding was not supported by another long-term follow-up study.[144]

The overall prevalence of cerebral palsy is approximately 1 in 2000 children. On the basis of the estimated incidence of perinatal cerebral vascular infarction, it might be expected that this condition is the cause of the neurologic deficit in up to 20% of children with cerebral palsy. This is supported by recent data showing that 22% of 377 infants with cerebral palsy showed focal arterial infarction on head imaging.[163]

PART 4

Hypoxic-Ischemic Encephalopathy

Malcolm I. Levene and Linda S. de Vries

Hypoxic-ischemic encephalopathy, severe enough to cause irreversible damage in the mature fetal brain, has an incidence of 1 to 2 per 1000 live births, but is 2 to 3 times more common in developing countries. Up to 25% of surviving infants may be irreversibly damaged by this condition. Neuroprotective therapy with hypothermia[11,29] has been shown to be effective in reducing the risk for disability and death in affected term babies and as such will offer an important therapeutic strategy to reduce brain damage in surviving babies. (See Management, later) Additional studies are needed to more clearly identify optimal candidates for therapeutic hypothermia.

I. Pathophysiology

Malcolm I. Levene

The immature brain is in some ways more resistant to hypoxic-ischemic (asphyxial) events than the central nervous system of the adult or older child. The reasons for this include a lower cerebral metabolic rate, particularly of glucose; immaturity in the development of the balance in functional neurotransmitters with potential neurotoxicity; and the plasticity of the immature central nervous system. Nevertheless, cerebral hypoxia-ischemia occurring in the fetus and newborn is a major cause of acute mortality and chronic neurologic disability in survivors. This is an even greater problem in the developing world than in Western nations. (See also Chapter 7.)

DEFINITIONS

Much confusion exists concerning the terminology of hypoxic-ischemic insults during fetal and neonatal life. The following discussion helps define the various widely used terms.

Hypoxic-Ischemic Encephalopathy

This term describes abnormal neurologic behavior in the neonatal period arising as a result of a hypoxic-ischemic event. The severity of hypoxic-ischemic encephalopathy (HIE) can be defined as mild, moderate, or severe depending on symptoms and signs; these are summarized in Table 40-6.[28]

Hypoxia or Anoxia

This denotes a partial (hypoxia) or complete (anoxia) lack of oxygen in the brain or blood.

Asphyxia

This is the state in which placental or pulmonary gas exchange is compromised or ceases altogether, typically producing a combination of progressive hypoxemia and hypercapnia. If the hypoxemia is severe enough, initially peripheral tissues (muscle and heart) and ultimately brain tissue develop an oxygen debt, leading to anaerobic glycolysis and production of a lactic acidosis. The lactic acid diffuses into the bloodstream, causing metabolic acidemia. This can be measured by blood gas analysis.

Ischemia

This is reduction (partial) or cessation (total) of bloodflow to an organ (e.g., the brain), which compromises both oxygen and substrate delivery to the tissue. Ischemia may occur as a result of perfusion failure alone (e.g., cardiac arrest or arterial infarction) or in the fetus in combination with hypoxia after a period of increasing compromise, as may happen during an abnormal labor. This usually results in increasing hypoxic acidosis with its consequent depressant effect on cardiovascular function.

SELECTIVE VULNERABILITY

It is impossible to generalize the diverse patterns of pathologic lesions seen after hypoxic-ischemic events. A number of factors influence the distribution of brain injury, summarized as follows:

- Cellular susceptibility
- Maturity
- Vascular territories
- Regional susceptibility
- Type of hypoxic-ischemic insult
- Others

There has been much debate as to the role of preexisting antenatal factors in exacerbating intrapartum HIE. An MRI study of term infants with neonatal encephalopathy has shown that the majority of the brain damage present in these babies occurred in the immediate perinatal period and was not the result of long-standing damage.[4]

Cellular Susceptibility

The neuron is the most sensitive cellular element to hypoxic-ischemic insult, followed by glia and cells comprising cerebral vasculature.

Maturity

Gestational age plays an important role in the changing susceptibility of cerebral structures to hypoxic-ischemic insult for a number of reasons, including rapid changes in neuronal development, changing vascular watersheds, and biochemical variables within cells, such as relative proportions of excitotoxic and inhibitory expression. Hypoxic-ischemic insult before 20 weeks' gestational age, such as may occur as the result of severe maternal illness, may lead to neuronal heterotopia or polymicrogyria[30] because the insult has hit the fetal brain during the stage of neuronal migration, which is not complete until 21 weeks of gestation (see also Part 1 of this chapter). Insults affecting the brain during midgestation (26 to 36 weeks) predominantly damage white matter, leading to periventricular leukomalacia (see also Part 2 of this chapter). Insults at term (35 weeks and beyond) result predominantly in damage to gray matter, particularly deep gray matter (posterior putamen and ventrolateral nucleus of the thalamus).

Vascular Territories

Watershed injury refers to tissue damage that occurs in regions that are most vulnerable to reduction in cerebral perfusion as the result of having the most tenuous blood supply. These tissues are at the furthest points of arterial anastomoses and are exposed to damage when perfusion pressure falls, usually as the result of impaired cardiac output and low blood pressure. Watershed areas change with advancing development. From 26 to 34 weeks' gestation, the periventricular white matter may be vulnerable because of its position between ventriculopetal and ventriculofugal arteriole distributions.

Periventricular leukomalacia has been described as being a watershed lesion, but more recently this has been challenged as the major factor in its pathogenesis.

TABLE 40–6 Clinical Staging of Hypoxic-Ischemic Encephalopathy

Variable	Stage I	Stage II	Stage III
Level of consciousness	Alert	Lethargy	Coma
Muscle tone	Normal or hypertonia	Hypotonia	Flaccidity
Tendon reflexes	Increased	Increased	Depressed or absent
Myoclonus	Present	Present	Absent
Seizures	Absent	Frequent	Frequent
Complex reflexes			
Suck	Active	Weak	Absent
Moro	Exaggerated	Incomplete	Absent
Grasp	Normal or exaggerated	Exaggerated	Absent
Doll's eye	Normal	Overactive	Reduced or absent
Autonomic function			
Pupils	Dilated, reactive	Constrictive, reactive	Variable or fixed
Respirations	Regular	Variations in rate and depth, periodic	Ataxic, apneic
Heart rate	Normal or tachycardia	Bradycardia	Bradycardia
Electroencephalogram	Normal	Low voltage, periodic paroxysmal	Periodic or isoelectric

Modified from Sarnat HB, et al: Neonatal encephalopathy following fetal distress: a clinical and electroencephalographic study, *Arch Neurol* 33:695, 1976.

In the term brain, a cortical watershed area (the parasagittal region) is present between the three main arteries supplying each hemisphere. The paracentral gyrus appears to be most vulnerable, with less sensitivity in the posterior parietal-preoccipital watershed area. The motor cortex is particularly liable to watershed injury, accounting for the observation that spastic cerebral palsy is the most common major sequela to hypoxic-ischemic insult at term. By corollary, the hippocampus, temporal lobe, and occipital lobes are most resistant to this type of insult. Volpe and colleagues,[32] using positron emission tomography to measure regional cerebral bloodflow in 17 full-term asphyxiated newborns, found a consistent decrease in bloodflow to the parasagittal region of both cerebral hemispheres in most of the infants.

The depths of the sulci are also sensitive to hypoxic-ischemic insult as the result of being watershed areas at term. Reduction in perfusion in small vessels at the base of sulci during hypoxia-ischemia leads to columnar necrosis and may lead to ulegyria in the older child's brain.

Arterial infarction (stroke) causes a characteristic pattern of damage on histologic examination wherein all cell elements die rather than just neurons, which bear the major burden of hypoxic-ischemic insult. Adverse perinatal events are reported to have been present in 46% of cases of arterial infarction,[19] but the relationship is probably not causal in most cases. In a group of 124 infants with neonatal encephalopathy, only 5% had a stroke lesion identified.[25] Infarction of a major cerebral artery should not necessarily be considered to be due to a hypoxic-ischemic insult because thrombosis and embolus are more common etiologic factors. The lesions typically involve the cerebral cortex and subcortical white matter, primarily in the territory of the middle cerebral artery and rarely in the distribution of the basilar artery.

Regional Susceptibility

Some regions of the brain are particularly sensitive to hypoxic-ischemic insult owing to the vascular factors discussed previously, but high metabolic rates of individual nuclei may predispose them to damage during cerebral hypoperfusion. This may account for the susceptibility of the posterior and lateral thalamic nuclei to damage after acute total asphyxia. Another factor accounting for regional variability to hypoxia-ischemia is the distribution of glutamate excitotoxic receptors. Regional cerebral glucose use also has been investigated with positron emission tomography after perinatal cerebral hypoxia-ischemia. Doyle and colleagues[6] investigated five newborns with positron emission tomography, using [18F]fluoro-2-deoxyglucose as the positron-emitting isotope. Localized decreases in cerebral glucose use were seen, corresponding to areas of hypodensity in cerebral gray and white matter structures noted on computed tomography (CT) scans. As with the cerebral bloodflow data, the alterations in regional cerebral glucose use presumably represented corresponding regions of tissue necrosis in which oxidative metabolism had declined below the rate of normal tissue.

Types of Hypoxic-Ischemic Insult

Animal studies on primates have modeled two different patterns of hypoxic-ischemic insult and have shown different patterns of neuronal injury depending on the type of insult.[3,20] Acute total asphyxia was produced in fetal monkeys by clamping the umbilical cord and preventing the animal from breathing. This produced injury to the thalamus, brainstem, and spinal cord structures. The longer the duration of the acute insult, the more extensive was the damage in these regions. Little damage was reported in higher structures.[20]

The second model attempted to mimic a partial asphyxial insult lasting 1 to 5 hours.[3] This produced damage predominantly in the cerebral hemispheres and particularly in the watershed distribution (see Vascular Territories earlier), often with sparing of brainstem, hippocampus, and temporal and occipital lobes. Damage was also seen not uncommonly in the basal ganglia and the cerebellum. In half the animals studied, significant asymmetry was seen between damage to the two hemispheres.

Others

Other types of hypoxic-ischemic insults include maternal fever during labor, which may accelerate fetal brain injury, fetal starvation with reduction in intracerebral glucose availability, sepsis, and twinning. The effects of these factors may act through one or a number of the variables discussed previously.

NEUROPATHOLOGY

For the reasons given previously, there are no consistent neuropathologic features of hypoxic-ischemic injury; rather, these vary depending on the type and duration of the insult and the gestational age of the child at the time of the insult. The pathologic features evident on examination also depend on the interval between the insult and death. If death occurs in close proximity to the hypoxic-ischemic insult, few if any changes may be seen, but if survival is prolonged for hours or days, then the neuropathologic features become more apparent as they develop in a temporal sequence. The following represent some of the more consistent features of hypoxic-ischemic injury.

Cerebral Edema

Brain edema is thought to occur frequently in infants who have sustained a severe cerebral hypoxic-ischemic insult, and is widely reported in autopsy studies. Cellular edema develops within an hour of the insult and resolves by 7 days after its onset.[30] In primate studies of intrapartum asphyxia, partial intermittent hypoxia-ischemia with marked and prolonged hypoxemia was associated with severe edema in all cases, whereas brain swelling was not a feature of severe, acute, total hypoxic-ischemic insults.[21] Edema particularly affects white matter and probably accounts for the abnormal signal on magnetic resonance imaging (MRI) seen in the region of the posterior limb of the internal capsule (see Neuroimaging later). Because of the higher water content in the neonatal brain cerebral edema cannot be reliably detected by magnetic resonance imaging until 24 hours after the event. The edema typically resolves by 7 days after onset. If the brain damage has been widespread and severe, on gross examination the brain appears swollen, with slitlike lateral ventricles, widening and flattening of the cerebral gyri with associated obliteration of the sulci, and herniation of hippocampal structures. In the most severe cases, herniation of the cerebellar tonsils and vermis through the foramen magnum has been described, but this is seen rarely in clinical practice.

Cellular Responses

Different cell lines in the brain react in varying ways to an acute hypoxic-ischemic insult. Neurons may undergo either necrosis or apoptosis (see Pathophysiology of Perinatal Hypoxic-Ischemic Brain Damage later). The nature of these two mutually exclusive processes can be distinguished to some extent by histologic staining. In necrosis, sections stained with hematoxylin and eosin show changes from 5 to 6 hours after the injury. Nuclear membranes degenerate, with release of nuclear chromatin and a secondary inflammatory reaction.[30]

Microglial cells (brain macrophages) respond rapidly within 2 to 3 hours after a hypoxic-ischemic insult and undertake the function of ingesting and lysing dead tissue. Activated microglia express a number of cytoxic cytokines. Hemoglobin released from damaged red cells is mobilized in this way, leaving residual hemosiderin present in the macrophage. Microglial cells present in the dentate gyrus are a reliable indication of previous hypoxic-ischemic insult in infants younger than 9 months of age.[5]

Glial cells respond to hypoxic-ischemic insult by enlarging, proliferating, and later developing fibrillary processes with the expression of glial fibrillary acidic protein, which can be recognized by specific staining. A glial response occurs from 17 weeks of gestational age.[30]

Calcification

Deposition of calcium in damaged neurons is commonly seen after hypoxic-ischemic insult and, if extensive enough, may be apparent on brain imaging. Insults other than those due to hypoxia-ischemia may also cause extensive calcification, including viral infection and certain metabolic disorders.

Chronic Lesions

Cerebral atrophy is the end stage of cellular loss in the brain. Atrophy affects particularly vulnerable areas of the brain (described earlier under Selective Vulnerability). Various specific forms of end-stage pathologic lesions have been recognized in the brain for many years.

Status marmoratus describes a patchy, marble-like appearance of the basal ganglia and thalamus that may develop approximately 6 months after a severe perinatal hypoxic-ischemic insult. Histologic study shows abnormal myelination of glial bundles rather than neurons.

Ulegyria refers to a particular form of pathology seen in the depths of the cortical sulci and is probably due to a particular watershed vulnerability (see Vascular Territories earlier). The chronic phase of this process produces the appearance of mushroom-like gyri because of loss of deep gray matter in the sulci.

SYSTEMIC ADAPTATION TO HYPOXIC-ISCHEMIC INSULT

Severe fetal hypoxic-ischemic injury affects the entire organism, and these effects have been well studied in animal models. Compromise resulting in hypoxic-ischemic injury may occur at any time during pregnancy, the birth process, or the neonatal period. The pattern of brain damage is reflected by the gestational age of the fetus at the time that the injury occurs. Fetal hypoxic-ischemic injury may result from maternal, uteroplacental, or fetal problems (Box 40-5). The

BOX 40–5 Causes of Fetal Hypoxic-Ischemic Insult

MATERNAL
- Cardiac arrest
- Asphyxiation
- Severe anaphylactoid reaction
- Status epilepticus
- Hypovolemic shock

UTEROPLACENTAL
- Placental abruption
- Cord prolapse
- Uterine rupture
- Hyperstimulation with oxytocic agents

FETAL
- Fetomaternal hemorrhage
- Twin-to-twin transfusion syndrome
- Severe isoimmune hemolytic disease
- Cardiac arrhythmia

fetus may survive maternal hypoxia-ischemia such as transient hypoxia or hypotension. Correctable placental factors include hyperstimulation with oxytocic agents or intermittent cord compression, but these may cause irreversible brain damage before recovery occurs.

Brain damage as the result of in utero hypoxic-ischemic insult has been described.[30] Occasionally, there is a history of a catastrophic maternal illness, such as suffocation, anaphylaxis, or major physical trauma. In other situations, the antecedent pathogenic event is confined to the fetus, with or without an associated abnormality of the uteroplacental unit. Whatever the cause of the cerebral hypoxia-ischemia, the neuropathologic consequence is often devastating.

In the mature fetus, a period of mild to moderate hypoxemia produces a consistent pattern of responses (Fig. 40-61A).[1] Initially, there is fetal bradycardia with compensatory increase in stroke volume leading to an immediate rise in blood pressure, and in particular an increase in perfusion to the brain and other vital organs at the expense of the rest of the body. With ongoing hypoxemia, the fetal heart rate gradually increases to prehypoxic levels, but the blood pressure and carotid bloodflow remain elevated above prehypoxemic levels. The fetus is very resistant to mild or moderate hypoxemia and normal cardiovascular function will be maintained for up to an hour even with a $Pa{O_2}$ of 15 mm Hg. If only moderate hypoxia is maintained, cerebral perfusion will remain normal, but if the situation persists for weeks then fetal growth restriction will occur. If moderate hypoxia is unrelieved, metabolic acidosis eventually develops with further adverse effects on physiologic and cellular integrity.

As the hypoxic insult becomes more severe, changes in regional cerebral bloodflow occur. The brainstem is able to extract sufficient oxygen to maintain metabolism despite very low $Pa{O_2}$ at the expense of the cerebrum. Failing myocardial function may cause a fall in cardiac output, and the watershed areas of the cerebral hemispheres are most exposed to damage (see Vascular Territories earlier).

In some cases, the fetus sustains a much more acute hypoxic-ischemic insult, as may occur during cord prolapse or uterine rupture. The physiologic effects are shown in Figure 40-61B. Under these circumstances, severe fetal bradycardia develops within a minute of the total asphyxial event, with an initially marked rise in blood pressure and carotid vascular resistance. In contrast to the more chronic situation, there is a reduction in cerebral bloodflow that is further exacerbated as blood pressure starts to fall owing to myocardial failure with unrelieved acute insult. This type of insult is likely to damage the basal ganglia and brainstem, in contrast to the more chronic insult, which leads to damage in the cerebrum.

Preconditioning

Preconditioning describes reduced sensitivity of the immature brain to injury depending on whether it has been exposed to previous nondamaging hypoxic events some hours before the main hypoxic-ischemic insult. Preconditioning of immature rat pups by exposure to moderate hypoxia before hypoxia-ischemia appears to be neuroprotective. Preconditioning may work through a number of pathways including induction of antiapoptotic genes, stimulation of growth factors (e.g., IGF), nitric oxide (NO), and free radical scavengers.

PATHOPHYSIOLOGY OF PERINATAL HYPOXIC-ISCHEMIC BRAIN DAMAGE

The most important advance in the neurobiology of hypoxic-ischemic brain damage in recent years has been the gradual (and as yet incomplete) unraveling of the processes leading to neuronal death. Our increasing understanding of these molecular and cellular changes is leading to strategies aimed at neuroprotection once a potentially damaging insult has occurred.

Acute hypoxic-ischemic insult leads to events that can be broadly categorized as early (primary) and delayed (secondary) neuronal death. The term *secondary* recognizes that many processes are involved and may extend up to 72 hours or even longer after the acute insult. Early neuronal death is predominantly due to necrosis, and delayed cell death is predominantly apoptotic.

Early or primary neuronal damage occurs as a result of cytotoxic changes due to failure of the microcirculation, inhibition of energy-producing molecular processes, increasing extracellular acidosis, and failure of Na^+/K^+-adenosine triphosphatase (ATPase) membrane pumps, which results in excessive leakage of Na^+ and Cl^- into the cell with consequent accumulation of intracellular water (cytotoxic edema). Free radical production is also initiated, which further compromises neuronal integrity. If not reversed, these processes lead to neuronal death within a short time of the acute insult, but recovery and reperfusion as occur with resuscitation fuel the pathways to late (secondary) neuronal damage through a relatively large number of known pathophysiologic mechanisms.

Secondary Neuronal Death

A complicated cascade of intracellular events is triggered by the initial hypoxic-ischemic insult, which results in either cell necrosis or apoptosis (Fig. 40-62).[1]

Glutamate Injury (Excitotoxicity)

Excessive neuroexcitatory activity occurs as a result of the asphyxial event and this is mediated through glutamate toxicity. Glutamate activates N-methyl-D-aspartate (NMDA) receptors, which in turn cause calcium channels to open in an unregulated manner with excess entry of intracellular Ca^{2+}. In high concentration, this ion activates lipases, proteases, endonucleases, and phospholipase C, which in turn break down organelle membranes. This sets up a variety of abnormal processes with release of free radicals, including $NO^{\bullet}$ and superoxide ions. This has further adverse effects on cell membranes and leads to mitochondrial failure with the release of caspase-3 and eventual DNA fragmentation, poly (ADP-ribose) polymerase (PARP) which causes further energy failure of intracellular membrane function. This process also triggers an apoptotic response in the cell.

Free Radical Formation

Unstable free radicals cause peroxidation of unsaturated fatty acids, and because the brain is especially rich in polyunsaturated phospholipids, it is especially susceptible to free radical attack. Mechanisms for quenching and inhibiting free radical production exist within the brain, but in the immature organ these mechanisms may be underdeveloped. Consequently, the human neonatal brain is at particular risk for free radical formation. Brain arteriole endothelium is the main source of free radical production by the action of xanthine oxidase, but free radicals are also produced by activated neutrophils, microglia, and intraneuronal structures. During reperfusion, free radical production from the arteriolar endothelium results in blood-brain barrier leakage and release of platelet-activating factor, platelet adhesion, and neutrophil accumulation.[14] This has the effect of reducing cerebral reperfusion bloodflow with secondary failure to provide substrate to the brain.

Two particularly important mechanisms that expose the newborn brain to free radical attack are the presence of free iron and the presence of NO. Free iron that is not bound to protein is found in higher concentration in the immature animal because of low transferrin levels. Free iron catalyzes mildly reactive oxygen species to more toxic free radicals. There is evidence that after a hypoxic-ischemic insult there is an increased presence of intraneuronal free iron within the first 24 hours[22] that persists for several weeks.

NITRIC OXIDE

NO is produced by three isoforms of the enzyme nitric oxide synthase (NOS), designated neuronal (nNOS), endothelial (eNOS), and inducible (iNOS). NO production is accelerated by intracellular Ca^{2+} influx and in excessive concentrations is neurotoxic. It is thought that up to 80% of N-methyl-D-aspartate toxicity is mediated through NO. NO also combines rapidly with superoxide to produce peroxynitrous acid, which gives rise to the free radical peroxynitrate. Excessive NO can cause DNA strand breaks and induce neuronal apoptosis mediated through caspase-3 activation. Studies on immature animals rendered nNOS-depleted, reduced injury in brain regions usually rich in nNOS activity.[9,10] This beneficial effect has been shown to be due to caspase-3 inhibition.[8] iNOS has also been reported to aggravate injury in the immature brain.[15]

Apoptosis

See also Part 1 of this chapter.

Apoptosis or programmed cell death is now recognized to be the major cause of neuronal death. It can be distinguished histologically from necrosis by shrinkage of affected cells with retention of the cell membrane. By contrast, necrosis is associated with cell rupture, which induces secondary inflammatory processes. DNA degradation develops in the apoptotic cell, giving a characteristic ladder appearance on gel electrophoresis.

Apoptosis is a gene-regulated process,[7] and both proapoptotic and antiapoptotic genes influence the process, *including BCL2, Bax, APAF1,* and the caspase gene family. In particular, the antiapoptotic gene *cJUN* is thought to trigger the process.[7] A major role in the apoptotic mechanism is played by the caspase family of proteins, with caspase-3 identified as the "execution protein." Inhibitors of caspase can block apoptosis and attenuate injury.[33] Other factors that may initiate or accelerate apoptosis include intracellular alkalosis[26] and caspase-independent apoptosis-inducing factor.[35]

Cytokines

There is evidence that some proinflammatory cytokines (tumor necrosis factor-α, interleukin [IL]-1β, and IL-18) are activated after a hypoxic-ischemic insult in immature experimental animal models, and they may have neurotoxic properties.[13] All of these cytokines rely on caspase-1 as a converting enzyme for full activation. Caspase-1 has also been shown to be an important mediator of neonatal brain injury.[17] After hypoxic-ischemic insult, widespread expression of caspase-1 and IL-18 protein in microglia was found.[13] IL-18-deficient mice had significantly less brain injury than wild-type mice, suggesting that IL-18 may have an essential function in the pathway of events leading to posthypoxic ischemic brain injury.[13] These data suggest that hypoxic-ischemic insult may initiate an inflammatory response in the absence of infection, leading to neuronal injury.

Studies in animals and humans have shown that exposure to infection (gram-negative bacteria in animal models) and chorioamnionitis in pregnant women significantly exacerbate clinical and neuronal injury.[2,8]

Human Studies

New technologies have given considerable insight into the time scale of these events in human infants who have been subject to a presumed severe clinical asphyxial event before delivery. In the early 1980s, magnetic resonance spectroscopy showed a consistent pattern of metabolic disturbance in the brain.[27,34] The ^{31}P magnetic resonance spectroscopy spectra in affected term infants were usually normal within the first 6 hours after birth, suggesting that mitochondrial phosphorylation had initially recovered with resuscitation. By 12 to 24 hours, there was a significant decline in the energy ratio of phosphocreatine to inorganic phosphate (PCr/Pi), with a further decline in the most severely affected infants at 48 to 72 hours. In some infants, recovery occurred to normal values within 7 days. The delayed fall in PCr/Pi ratio represents secondary energy failure. ^{1}H magnetic resonance spectroscopy in other groups of asphyxiated infants showed a rise in intracerebral lactate peak simultaneous with the fall in PCr/Pi ratio.[12,23] Studies sampling specific voxels in the affected brain show regional differences, with increased lactate concentrations particularly in the thalamus compared with the occipitoparietal white matter.[12]

Near-infrared spectroscopy has also been used in the term newborn to study cerebral blood volume and bloodflow after severe presumed hypoxic-ischemic insult. These studies have shown a marked increase in blood volume and bloodflow in the brain with loss of normal CO_2 reactivity,[18,24] which suggests that secondary energy failure compromises cerebral arteriolar function with failure of small vessel reactivity that results in vasodilation and maximum bloodflow.[32]

II. Assessment Tools

Linda S. de Vries

Many different tools have become available to aid in the more precise prediction of neurodevelopmental outcome in the full-term infant with HIE. Both neurophysiology and neuroimaging play an important role and are discussed separately.

NEUROPHYSIOLOGY

See also Part 5.

Neonatal electroencephalography (EEG) is a well-recognized method to assess brain integrity after hypoxia-ischemia that results in neonatal encephalopathy. In newborn infants, the EEG commonly uses 16 channels and is in most centers only performed during the day; it requires skilled technicians and highly trained and experienced neurophysiologists to interpret the recordings. The 16-channel EEG provides detailed information and when performed with simultaneous video recording, helps to make a distinction between clinical and subclinical seizures.[45,79] A recent study showed that less than 10% of neonatal seizures were correctly identified by the neonatal staff, compared with simultaneous video-EEG recordings.[81] Normal and severely abnormal results on EEG have important predictive value. Normal traces almost invariably predict a normal outcome, whereas persistent, severely abnormal traces predict an adverse outcome (Fig. 40-63).[62,106] Prediction in children with mild to moderate EEG abnormalities is less reliable and requires sequential recordings. EEG activity is fully differentiated in full-term infants. During quiet sleep, a discontinuous pattern (tracé alternant) alternates with a high-voltage continuous delta pattern. In wakefulness, the EEG is characterized by low-voltage mixed theta-delta activity. In active sleep, a mixed medium-voltage delta-theta activity is seen. Abnormalities on the EEG can be classified as background abnormalities, ictal abnormalities, and abnormalities in the organization of states and maturation.[62,74,75,103] Background pattern abnormalities are highly predictive of outcome (Fig. 40-64).[41,80] It should be taken into account that antiepileptic drugs can (transiently) affect sleep states and the background pattern, especially in children with severe encephalopathy.[103] The following background patterns can be recognized: isoelectric and extremely low voltage (less than 5 μV); burst suppression pattern, with long periods of inactivity (usually longer than 10 seconds) mixed with bursts of abnormal activity. Outcome is especially poor with long periods of inactivity[40,77] and brief periods of bursts (less than 6 seconds) with small-amplitude bursts and interhemispheric asymmetry and asynchrony.

To overcome the problem of difficult access and lack of continuity, a continuous monitoring device is now increasingly being used, the amplitude-integrated EEG (aEEG). This simple device was initially used as a single-channel EEG from a pair of parietal electrodes. The EEG signal is first amplified and passed through an asymmetric band-pass filter that strongly attenuates activity below 2 Hz and above 15 Hz to minimize artifacts from electrical interference. The EEG processing

involves semilogarithmic amplitude compression, rectification, smoothing, and time compression.[85] The digital devices also provide the raw EEG and can use more than a single channel. Easy around-the-clock access and easy interpretation based on pattern recognition have led to an increase in continuous monitoring of brain activity in the neonatal intensive care unit. Several groups have compared simultaneous aEEG with a 16-channel EEG recording.[104] A good correlation was noted for the background pattern (Fig. 40-65). In a later study comparing a standard EEG with a single-channel aEEG from the C3-C4 position and without display of the raw-EEG, only 12% to 38% (mean 26%) of individual seizures were detected.[97] Seizures that will not be detected with aEEG are short seizures, low-amplitude seizures, and focal discharges (Fig. 40-66). Sensitivity of seizure recognition can be considerably improved when using a two-channel bilateral centroparietal aEEG recording with access to the corresponding raw EEG.[96] While the sensitivity for detecting seizures in one or two-channel aEEG recordings without access to the raw EEG was 27% to 56%, 76% of the seizures were detected when using two aEEG channels with the corresponding raw EEG. Performing at least one 16-channel EEG during the aEEG recording is therefore strongly recommended. Use of continuous aEEG recording provided information about the improvement that can occur in infants with very poor background patterns immediately after delivery. Recovery of a burst suppression pattern within the first 24 hours was sometimes noted to be associated with a normal outcome.[88] On the other hand, children with a continuous voltage pattern could deteriorate after 24 hours during a period of secondary energy failure, showing deterioration of their background pattern and late onset of seizures. In most infants, however, a good prediction of later neurodevelopmental outcome could be made on the basis of the aEEG background pattern obtained at 6 or even 3 hours after birth.[55,103] The early predictive value of the background pattern assessed with this technique has led to its use for selection of newborn infants in intervention studies, such as the hypothermia study.[58] A longer recording will also allow assessment of the presence, quality, and time of onset of sleep-wake cycling (SWC). The presence, time of onset, and quality of SWC reflects the severity of the hypoxic-ischemic insult to which newborns have been exposed.[83] The time of onset of SWC helps predict neurodevelopmental outcome based on whether SWC returns before 36 hours (good outcome) or after 36 hours (bad outcome). It was recently shown that recovery of background activity tends to be slower during hypothermia, and care should be taken when predicting outcome. The positive predictive value for predicting a poor outcome during the first 3 to 6 hours was only 59% in the infants receiving hypothermia compared to 84% in those with normothermia. Infants

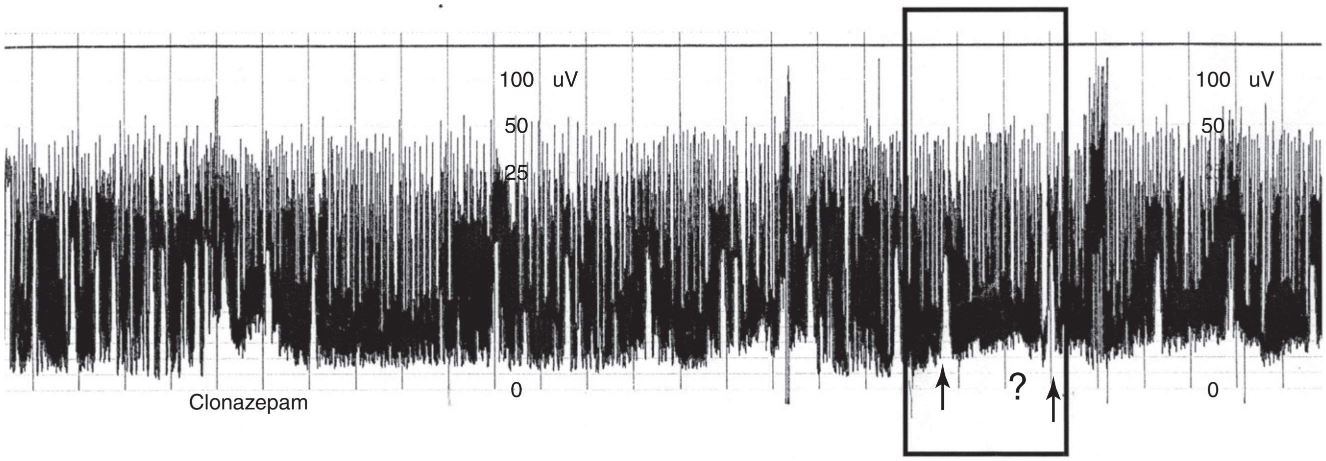

Figure 40–65. Same child as in Figure 40-64 showing burst suppression pattern on the amplitude-integrated electroencephalogram (aEEG). The box indicates a period of simultaneous EEG recording. The two arrows indicate an electrical discharge recognized by aEEG, and the question mark indicates a period when a focal discharge was seen only on the standard EEG (see Fig. 40-66).

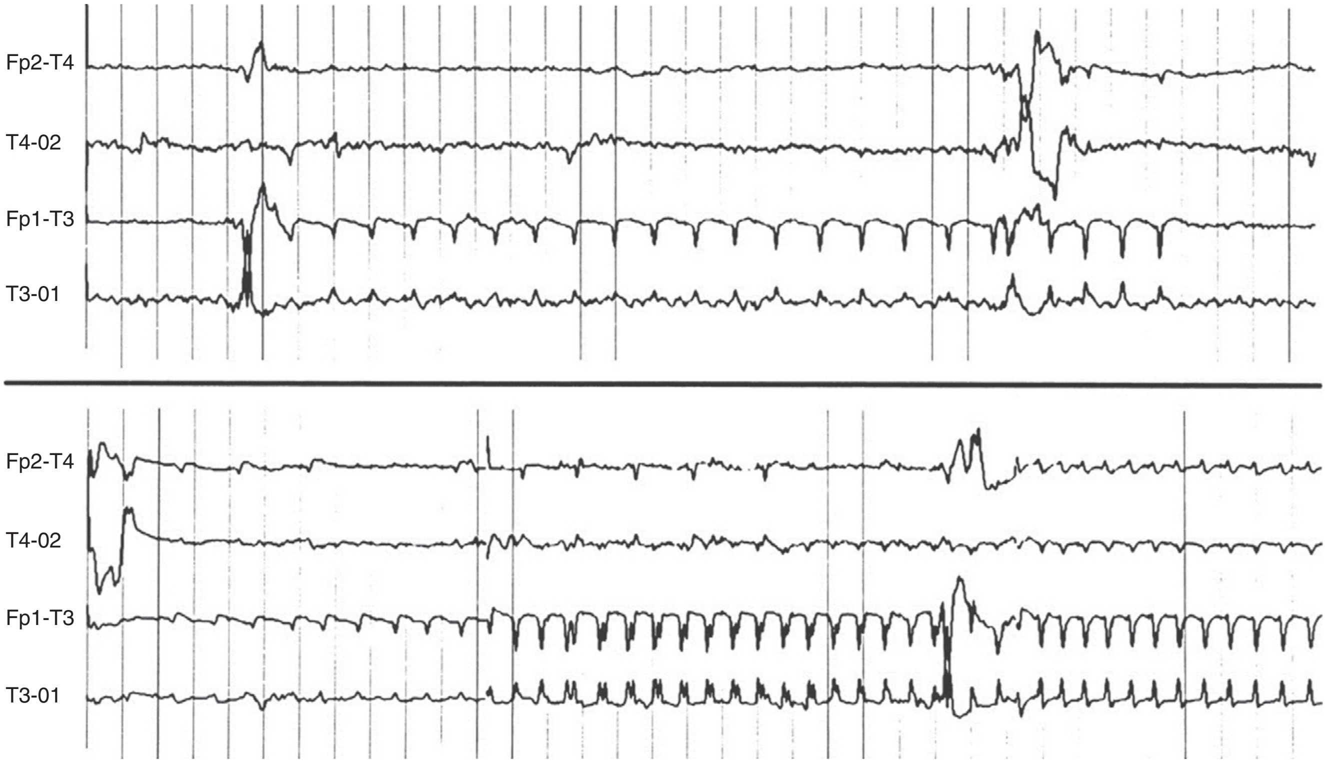

Figure 40–66. *Top,* Focal discharge, origin left temporal, not detected on amplitude-integrated electroencephalogram; *bottom,* focal discharge with spread. *(From Toet MC, et al: Comparison between simultaneously recorded amplitude integrated EEG [Cerebral Function Monitor] and standard EEG in neonates,* Pediatrics *109:772, 2002, with permission.)*

with a good outcome normalized their background pattern by 24 hours, but by 48 hours if treated with hypothermia. Similar observations were made by Hallberg and colleagues.[58a,101b]

The presence of subclinical seizures can be better evaluated using aEEG, and it was noted that newborns very often show electroclinical dissociation, especially after administration of the first drug given for clinical seizures.[45,95] Scher and colleagues[95] found that 58% of infants with seizures persisting after treatment with phenobarbitone or phenytoin showed uncoupling of electrical and clinical seizures (see also Part 5 of this chapter). Status epilepticus (ongoing seizure activity for at least 30 minutes) is not uncommon and was noted in 18% in a cohort monitored with continuous aEEG.[89] In this study, there was a significant difference in background pattern, as well as in duration of the status epilepticus between infants with a poor outcome, compared with those with a good outcome.

Efficacy of treatment of seizures was noted to be poor, as already reported by others using intermittent 16-channel EEGs.[45,84] The most commonly used drugs (phenobarbital and phenytoin) were shown to treat seizures effectively in less than half of patients when given as a single drug.[84] Other drugs, like lidocaine, were noted to be more effective, but are not yet widely used.[47,61,76] Off-label use of antiepileptic drugs like levetiracetam and topiramate is not uncommon.[98]

Long-term outcomes in children who had neonatal seizures vary considerably in reports.[46,60,75] This is probably due to differences in inclusion criteria and methods of diagnosing neonatal seizures. Postneonatal epilepsy is not uncommon (20% to 50%) and was noted to be especially common after subtle seizures.[48,71] In two studies using aEEG and treating clinical as well as subclinical seizures, postnatal epilepsy developed in only 8% to 9% of the survivors.[60,105] There is no agreement in the literature over whether neonatal seizures themselves can lead to damage of the immature neonatal brain. Electroclinical and electrographic neonatal seizures produce an increase in cerebral bloodflow velocity. It is suggested that electrographic seizures are associated with disturbed cerebral metabolism and that treatment of neonatal seizures until electrographic seizure activity is abolished may improve outcome.[44,88a]

Animal studies have shown that neonatal seizures can permanently disrupt neuronal development.[63,64,74] Seizures superimposed on hypoxic ischemia in rat pups were noted significantly to exacerbate brain injury.[108] On the other hand, antiepileptic drugs are not without side effects, and data from a study published in 2002 have shown apoptotic neurodegeneration in the developing rat brain at plasma concentrations relevant for seizure control in humans.[42]

EVOKED POTENTIALS

Evoked potentials can further aid in the prediction of neurodevelopmental outcome of full-term infants with HIE. Brainstem auditory evoked potentials (BAEPs) or brainstem evoked response and visual evoked potentials (VEPs) are technically easier to perform than somatosensory evoked potentials (SEPs).

BAEPs are responses generated in the auditory brainstem pathway after an acoustic stimulus (see also Chapter 42). They are used to assess both the peripheral sensitivity and the neurologic integrity of the auditory pathway. Seven positive waves can be recognized; these are indicated with Roman numerals. BAEPs are regarded as the most objective and reliable method of evaluating peripheral auditory function in neonates. Because perinatal asphyxia is a well-known risk factor for sensorineural hearing loss, BAEPs should always be performed in at-risk infants. Initial studies using BAEPs to predict neurodevelopmental outcome were not as consistent as those using SEPs and VEPs. An increase in the I through V peak latency, considered to represent brainstem conduction time, was noted to be of predictive value. When children were assessed again at 4 to 12 years, the sensitivity, specificity, positive predictive value, and false-negative rate of neonatal BAEPs for subsequent neurodevelopmental outcomes were 40.5%, 87.8%, 75.0%, and 59.5%, respectively.[68] More recent studies by the same group have used maximum-length sequence BAEPs with an increased repetition rate of clicks (90 to 910 per second) and have shown that this may be a better way to demonstrate the effect of HIE, which was most marked on day 3 (Fig. 40-67).[67]

The VEP is a gross electrical signal generated by the occipital area of the cortex in response to a visual stimulus. The stimulus can be either a diffuse flashing light or a patterned visual stimulus. In the neonatal unit, light-emitting diode goggles or small light-emitting diode screens are most widely used. The P200 and the N300 are the major components that can be recognized in the neonatal period. FVEPs (flash VEPs) are good predictors of cerebral visual impairment after perinatal asphyxia.[107] A high correlation between FVEPs and neurodevelopmental outcome was found by the same group.[101,107] Absent FVEPs carried a poor prognosis, whereas persistently abnormal FVEPs also predicted an abnormal outcome. Normal FVEPs, however, were not always associated with a good outcome, and FVEPs appeared to be more resistant than SEPs. When FVEP recording was performed within 6 hours after birth, a positive predictive value of 77% was found, slightly lower than for SEPs (82%) or aEEG (84%).[55] VEPs were recently shown to be predictive of cerebral visual impairment in full-term infants with symptomatic hypoglycemia and injury to the occipital visual cortex.[99]

SEPs are technically the most difficult to perform and by far the most time consuming. The median nerve is usually

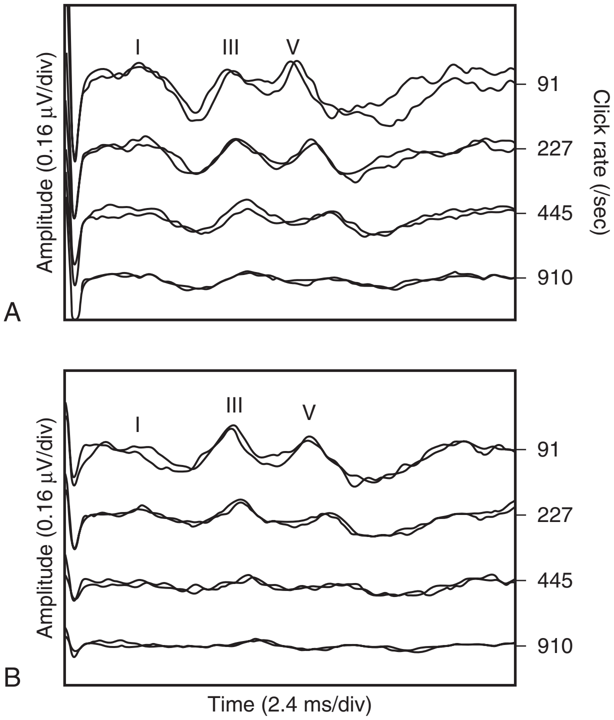

Figure 40–67. Sample recordings of the brainstem auditory evoked potential at 91, 227, 455, and 910 clicks per second. **A**, Normal term neonate. **B**, Asphyxiated term neonate; the amplitude of wave V is significantly reduced at 910 clicks per second. *(From Jiang ZD, et al: Maximum length sequence brainstem auditory evoked responses in term neonates who have perinatal hypoxia-ischemia,* Pediatr Res *48:639, 2000.)*

stimulated because this is better tolerated than stimulation of the tibial nerve. At the scalp, contralateral to the site of stimulation and overlying the primary somatosensory cortex, wave N19 is recorded, which is considered to be cortically generated. In the newborn, this component is usually referred to as N1. The predictive value of SEPs in full-term infants with HIE was first shown by Hrbek and colleagues[65] and has been confirmed since by several groups.[52,57,94,101] When comparing FVEPs and VEPs, some studies showed SEPs to be superior in the prediction of neurodevelopmental outcome. Because the predictive value within the first 6 hours after birth was noted to be similar for aEEG and evoked potentials, aEEG is preferred because of easy access, application, and interpretation.[55]

NEUROIMAGING

See also Parts 1 through 3 of this chapter.

As discussed earlier, certain regions of the brain are preferentially affected under different circumstances. Different imaging modalities can be used, but recent data have shown MRI to be superior compared with ultrasonography and CT.

Cranial ultrasonography has a poor reputation when it comes to assessment of abnormalities of the brain of the full-term infant with HIE. Ultrasonography can be helpful, however, especially when performed sequentially during the first week of life.[54,90] Changes in the thalami and basal ganglia may be subtle, but usually become more clear by the end of the first week of life.[54] Alterations of the signal in the white matter can sometimes be seen on admission, suggesting that the insult is of antenatal onset. More often, echogenicity develops gradually over a period of days. In severe cases, the ventricles are difficult to visualize owing to edema and are referred to as *slitlike*. A Doppler signal can be obtained during the ultrasonographic examination, at the level of the anterior or preferably the middle cerebral artery. Several studies have shown that an increase in diastolic flow, resulting in a reduced resistance index (less than 0.55) and an increase in cerebral bloodflow velocity (greater than 3 standard deviations), is associated with a poor neurodevelopmental outcome.[66,72] Changes usually developed after the first 24 hours after birth. Color Doppler flow across the sagittal sinus can be used to diagnose or exclude a sinovenous thrombosis.

CT is less sensitive than MRI for detecting changes in the central gray nuclei, which is the most common problem in full-term infants with HIE.[50] A decrease in attenuation of white matter may be difficult to differentiate from normal unmyelinated white matter. CT is still useful in experienced hands and especially in a child admitted after a traumatic delivery and suspected of having an extra-axial hemorrhage. In such cases, ultrasonography may miss these collections unless they are large with an associated midline shift. CT may be more accessible than MRI, and in the likelihood of possible surgical intervention, a CT can be done soon after admission.

MRI is the most appropriate technique to use and is able to show different patterns of injury.[78] The basal ganglia and thalami are involved in the first pattern, which is especially common after an acute sentinel.[37,82] An altered, sometimes reversed signal at the level of the posterior limb of the internal capsule can be seen during the second half of the first week, and this has been noted to be of very high predictive value for neurodevelopmental outcome (Fig. 40-68).[92] With the use of diffusion-weighted MRI, abnormalities in the thalami and basal ganglia can often be seen within days after birth, but the alterations in signal intensity may be more pronounced later during the first week (Fig. 40-69).[39] Calculation of apparent diffusion coefficients can be of further use to assess the severity of the insult.[93] Changes in the basal ganglia are often seen together with changes at the level of the central gyrus, and this combination carries a poor prognosis.[70] The second most common pattern of injury is injury to the watershed regions, which is especially well recognized with diffusion weighted MRI.[78] Signal intensity changes in the white matter can also be well recognized with MRI, as well as cortical highlighting. The severity of white matter abnormalities can vary from focal lesions, often with punctate white matter lesions, and these were recently noted to be especially common in infants with milder encephalopathy and of slightly lower gestational age.[73] White matter lesions can also be very diffuse with loss of gray-white matter differentiation, preceding cystic evolution. These more severe white matter abnormalities are often seen in association with abnormalities of the basal ganglia, and early changes on MRI correlate well with neonatal EEG, later MRI findings, and neurodevelopmental outcome.[41,51,91] Tanner and colleagues[100] used dynamic susceptibility contrast-enhanced MRI to calculate qualitative values of relative cerebral bloodflow. Values of regional cerebral bloodflow were generally larger in gray than white matter. Movement artifacts were common and only a small number of infants were studied during the first week of life.

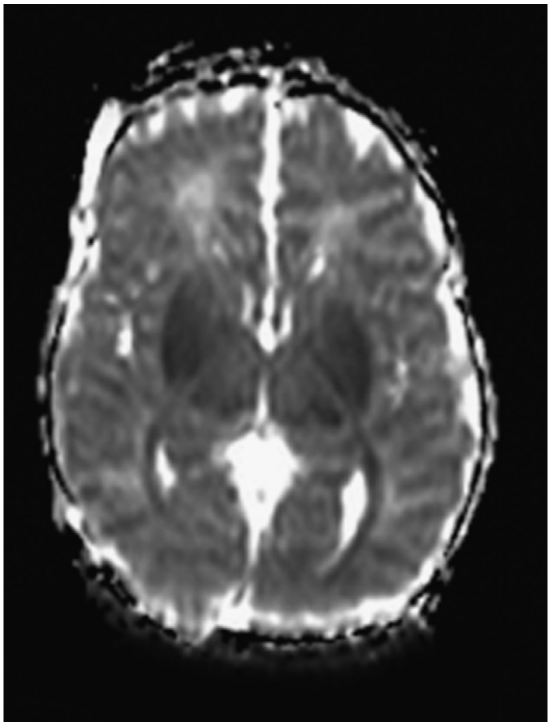

Figure 40–68. Magnetic resonance image, apparent diffusion coefficient map, performed on day 3 in a full-term infant with hypoxic-ischemic encephalopathy grade II. A decreased signal is seen in the lentiform nuclei, the ventrolateral thalami, and optic radiation.

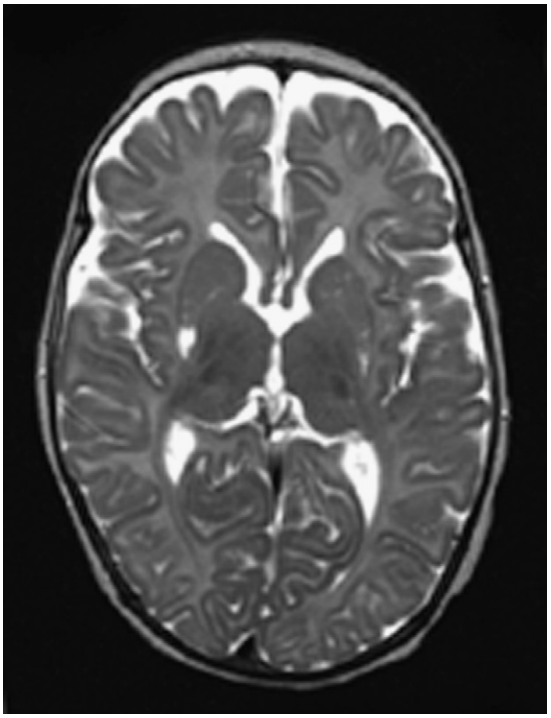

Figure 40–69. T2-weighted spin echo sequence at 3 months of age in the same child as in Figure 40-68. Cortical atrophy is noted anteriorly. Small areas with a signal intensity compatible with cerebrospinal fluid are seen at the level of the lentiform nuclei, more marked on the right side.

Focal ischemic lesions are also well detected using this technique. The middle cerebral artery, most often the left branch, is most commonly affected. Diffusion-weighted MRI allows detection of the area involved at a time when conventional MRI may not yet be very reliable. Involvement of the descending corticospinal tracts can be well visualized with diffusion-weighted MRI and is referred to as *pre-wallerian degeneration,* which is highly predictive of subsequent wallerian degeneration and development of a hemiplegia.[53,69] Magnetic resonance angiography can further aid in the visualization of abnormal flow across the artery involved in case of an embolism or dissection. The area of cavitation noted on a repeat scan performed a few months later usually is smaller than expected on the basis of the area of abnormal signal intensity seen on the initial scan, but the tissue surrounding the cavity is altered and shows gliotic scarring later in infancy. Sinovenous thrombosis was considered to be a rare condition, but with the introduction of MRI and MR venography, it is more often diagnosed.[108] Conventional MRI shows an increased signal in the sinus on a T1-weighted image, and magnetic resonance venography shows lack of flow across the sinus. The sagittal sinus, straight sinus, or the deep veins of the basal ganglia can be affected.[56] An associated unilateral thalamic hemorrhage can be present.[109] In such cases, prothrombotic factors should be checked (see also Part 3 of this chapter and Fig 40-58).

Metabolic assessment using proton or phosphorus spectroscopy can be performed during the MRI examination. This technique uses the intrinsic magnetic properties of some atomic nuclei (^{1}H, ^{31}P). The most commonly used nucleus for clinical applications is the proton (^{1}H) because it is the most abundant and strongest nucleus. N-acetylaspartate, creatine/phosphocreatine, choline-containing compounds, myoinositol, glutamine and glutamate, and lactate can all be recognized within the proton spectrum. The peaks described for the ^{31}P spectrum are β-ATP, α-ATP, and γ-ATP, PCr, phosphodiesters, inorganic phosphate (Pi), and phosphomonoesters. Depletion of ATP and an increase in Pi, associated with a change in the PCr/Pi ratio, have been reported using phosphorus spectroscopy.[49] A decrease in N-acetylaspartate and a high lactate peak have been reported for ^{1}H proton spectroscopy.[59,87] An increased lactate-to-creatine ratio (greater than 1) obtained within 18 hours after birth predicted neurodevelopmental impairment at 1 year of age with a sensitivity of 66% and a specificity of 95%.[59] In another study, the ratio of lactate to N-acetylaspartate was used, showing a sensitivity of 78% and a specificity of 90%.[36] Cerebral intracellular alkalosis was noted to persist for months after neonatal encephalopathy.[86] A comparison of proton spectroscopy and diffusion-weighted MRI on the first day after birth showed that proton magnetic resonance spectroscopy was better in accurately depicting the severity of injury at this early stage.[38] A recent meta-analysis comparing conventional MRI diffusion-weighted imaging and MRS as potential early biomarkers found deep gray matter Lac/NAA to be the most accurate quantitative MR biomarker within the neonatal period for prediction of neurodevelopmental outcome after neonatal encephalopathy.[101a]

Positron emission tomography has been infrequently used.[43,102] A study of regional cerebral metabolic rates of glucose (CMRgl) in six infants by Blennow and colleagues[43] showed localized increases in five, which were in good agreement with changes seen with other neuroimaging techniques. In another study of 20 infants, the deep subcortical areas, thalamus, basal ganglia, and sensorimotor cortex were identified as the most metabolically active brain areas. Total CMRgl were inversely related to the severity of HIE ($P < .01$).[102]

III. Management

Malcolm I. Levene

PRIMARY PREVENTION

Prevention of fetal asphyxia is far preferable to the prospect of managing the newborn who has suffered a hypoxic-ischemic insult in labor. The aim of modern obstetrics is to recognize the compromised fetus before irreversible organ damage occurs and rescue it from the hostile environment.

Electronic fetal monitoring (EFM) is widely used to identify hypoxic babies (see also Chapter 10). A Cochrane Review[110] of 12 randomized controlled trials showed a statistically significant decrease in the number of neonatal seizures in the infants born in the EFM group (RR 0.50; 95% CI 0.31-0.80). This effect was noted in only two of the larger studies, where the option of pH estimation was available for unfavorable traces. There was no significant difference in overall perinatal death rate (RR 0.85; 95% CI 0.59-1.23). These studies also showed a significantly increased risk of delivery by cesarean section in the EFM group (RR 1.66; 95% CI 1.30-2.13).

Follow-up of surviving infants was available in two studies and both failed to show any reduction in long-term neurologic adverse effects.

Fetal electrocardiogram (ECG) waveforms have been evaluated as a more sensitive method for detecting fetal hypoxia than EFM. Two different methods have been studied: the PR to R-R ratio and the ST waveform. In the PR to R-R ratio, there is normally a positive correlation between the PR interval and the R-R interval, so that when the heart rate increases, both the PR and R-R intervals shorten. The hypoxemic heart behaves differently, with shortening of the PR interval and lengthening of the R-R interval so that change in the PR to R-R ratio is a predictor of fetal heart hypoxic compromise. An alternative method assesses changes in the ST waveform in much the same way as exercise ECG assessment in adults with myocardial disease.

A Cochrane analysis of four randomized controlled trials of fetal ECG use in labor has been reported by Neilson.[155] All trials assessed fetal ECG as an adjunct to EFM alone in labor. The studies of ST waveform resulted in fewer babies born with severe metabolic acidosis ($\text{pH} < 7.05$) (RR 0.64; 95% CI 0.41-1.00), and fewer babies with neonatal encephalopathy (RR 0.33; 95% CI 0.11-0.95), although the numbers of babies with encephalopathy was very low when compared with standard EFM alone. There was no significant increase in numbers of cesarean section delivery or admissions to the neonatal unit. By contrast, analysis of PR interval showed no benefit in pregnancies monitored with this technique.

More recently a Cochrane review compared fetal pulse oximetry with EFM monitoring.[124] In the five trials published to date there was no overall reduction in cesarean section rate or neonatal outcome when EFM and oximetry were compared with EFM alone. One study reported a significant reduction in cesarean section rate in the group assessed by pulse oximetry following the detection of a nonreassuring EFM trace.

In summary, intrapartum assessment of severe hypoxia may result in improved condition at birth and reduce the risk of neonatal encephalopathy, but there is little evidence to support the notion that hypoxic-ischemic brain damage can be prevented.

RESUSCITATION

See also Chapter 26.

The key to resuscitation is to restore adequate oxygenation and perfusion of vital organs, particularly the brain. Systemic acidosis developing as a result of intrapartum asphyxia impairs cardiac contractility, but its effect on cerebral function is less clearly understood and there is some evidence that a degree of intracerebral acidosis may have a neuroprotective effect.[115]

Infants are born in unexpectedly poor condition and require immediate resuscitation. Most infants born in suboptimal condition can be anticipated (Box 40-6), and staff trained in neonatal resuscitation should be available at the birth. It is estimated, however, that approximately 20% of infants who require resuscitation do not fall into this group. The importance of expert resuscitation has been recognized and studied only comparatively recently, and every infant, wherever born, must have available to it personnel with expert resuscitation skills and all the appropriate equipment in good working order.

BOX 40–6 **Conditions in Which the Need for Resuscitation at Birth May Be Anticipated**

PRELABOR FACTORS

MATERNAL
Toxemia (eclampsia)
Diabetes mellitus
Drug addiction
Cardiovascular disease
Infectious disease
Collagen vascular disease

UTEROPLACENTAL
Placental abruption
Umbilical cord prolapse
Placenta previa
Polyhydramnios
Premature rupture of the membranes

INTRAPARTUM FACTORS
Isoimmunization
Multiple birth
Preterm birth
Cardiopulmonary abnormalities
Abnormal presentation
Precipitous delivery
Fetal distress
Thick meconium staining
Prolonged labor
Difficult forceps delivery
Intrauterine growth restriction
Prolonged pregnancy

SYSTEMIC MANAGEMENT

The diving reflex occurs during experimental asphyxia to maintain blood flow to vital organs such as the brain at the expense of less-vital organs. This is the basis of systemic complications after a clinically significant hypoxic-ischemic insult, and the heart, kidneys, and liver are the most vulnerable organs. Almost all babies with hypoxic-ischemic encephalopathy (HIE) show compromise in at least one organ system outside the brain.[166] The clinical course after a hypoxic-ischemic event in labor is unpredictable, so problems should be anticipated and the infant appropriately observed by trained staff in a clinical environment. Hypoxic-ischemic insult affects the whole organism and any organ system may be compromised. Brain-oriented management is discussed later; this section discusses management of systemic complications.

The Renal System

Renal impairment is reported to occur in 23% to 70% of asphyxiated infants.[166] Acute renal failure (plasma creatinine greater than 130 μmol/L [1.2 mg/dL] for at least 2 consecutive days) is reported in 19% of asphyxiated infants of greater than 33 weeks' gestation. In a study using a more sensitive measure of renal tubular function (N-acetylglucosaminidase), there was a relationship between elevated N-acetylglucosaminidase levels and degree of HIE in the infant.[166]

Because of the fear of renal failure and fluid overload, many clinicians have adopted a policy of fluid restriction in asphyxiated newborn infants, but there is no evidence that normal fluid volumes contribute to cerebral edema in the newborn. Fluid restriction is necessary in infants who have inappropriate antidiuretic hormone secretion or those with known renal tubular impairment. Fluid intake in these infants should be titrated against measurements of the infant's serum and urinary electrolytes.

Oliguria is managed by careful maintenance of fluid balance with daily measurement of plasma and urinary creatinine levels, and serum and urinary electrolytes, as well as daily assessment of the infant's weight. Acute renal failure and anuria lasting more than a day should be initially managed conservatively (see Chapter 36). Chronic renal failure and the need for dialysis is extremely rare in severely asphyxiated full-term infants.

Cardiovascular System

Myocardial contractility is impaired after hypoxic-ischemic insult, causing a significant reduction in cardiac output, hypotension, and further impairment of cerebral blood flow and perfusion of other organs. Myocardial dysfunction detected by Doppler ultrasonography has been shown to occur in 28% to 50% of asphyxiated newborn infants.[114,160] Other cardiac pathologic processes recognized to occur after a severe hypoxic-ischemic insult include acute cardiac dilation with functional tricuspid valve regurgitation, myocardial ischemia present on ECG assessment, and ischemic necrosis of papillary muscle. Tropinin has been suggested as a marker for perinatal myocardial damage but little objective data are available.

Hypotension is a common complication after severe hypoxic-ischemic insult,[166] and volume support is often ineffective in restoring normotension. The inotrope dopamine (5 to 15 μg/kg per minute) has been shown to be more effective in restoring blood pressure in asphyxiated infants.

Hepatic and Gastrointestinal Systems

Elevated liver enzymes occur in 80% to 85% of asphyxiated full-term newborn infants during the first week of life.[138,166] Irreversible liver damage appears to occur very rarely after birth asphyxia. Necrotizing enterocolitis is a well-recognized complication in asphyxiated infants, but is seen relatively rarely due to this cause.

Hematologic Complications

Coagulation impairment is relatively common after a severe asphyxial insult. The bone marrow may be transiently damaged, leading to thrombocytopenia. Disseminated intravascular coagulation is also well recognized to occur after birth asphyxia, with low levels of factor XIII and elevated thrombin-antithrombin complexes; D-dimer, fibrin, and fibrinogen degradation products; and soluble fibrin monomer complexes.[170]

Coagulation impairment should be anticipated and screening for hematologic abnormalities undertaken in all severely asphyxiated newborn infants. Supportive treatment with platelets, vitamin K, or clotting factors may be indicated by specific abnormalities on the coagulation screen. The management of disseminated intravascular coagulation is controversial, but there is no indication for systemic heparinization (see also Chapter 46).

BRAIN-ORIENTED MANAGEMENT

Hypothermia has become a standard of care for babies with moderate to mild HIE and four large studies have now confirmed the effectiveness and safety of this technique in preserving cerebral function.[111,126,132,167] This technique is discussed in detail below. In addition to hypothermia, careful attention must be paid to maintain cerebral homeostasis by anticipation of complications that may have a direct or indirect effect on brain function and recovery after a severe hypoxic-ischemic insult. More standard brain-specific complications affecting the infant after a severe hypoxic-ischemic insult are discussed here.

Glucose

Hypoglycemia has been shown to be an additional adverse factor for the immature brain in conjunction with a hypoxic-ischemic insult. Immature hypoglycemic animal models subjected to anoxia have a considerably increased mortality rate compared with anoxic, normoglycemic animals.[180] The presence of ketone bodies as an alternative brain fuel ameliorates this effect despite low levels of circulating glucose.[180] The facilitative glucose transporter proteins (GLUT1) transports glucose across the blood-brain barrier, and related proteins (GLUT3 and 45-kd GLUT3) mediate transport into the neuron and glial cells, but these proteins are in low concentration in the immature brain. Hypoxic-ischemic insult initially enhances both GLUT1 and GLUT3 expression in the brain, but GLUT3 decreases after 72 hours, associated with extensive cellular necrosis.[178] Asphyxia initially increases cerebral metabolic rates of glucose (CMRgl), and consumption of glucose during the hypoxic-ischemic insult causes depletion of intracerebral glucose. Very limited numbers of infants have been studied after asphyxial insults by positron emission tomography, with conflicting results. In five term infants, CMRgl was increased 2 to 3 days after the insult,[117] whereas another study of CMRgl in 20 human asphyxiated infants showed a high correlation between the more severe degree of HIE and lowest values of CMRgl.[173] These low levels were obtained at a median age of 11 days, which was later than the first study and may account for the differences in values.

Studies have shown that there are major differences in behavior of the mature and immature brain to glucose infusion.[176] The infusion of glucose in the immature organism, unlike in adults, before a hypoxic-ischemic event appears to have protective effects compared with subjects not given sugar supplementation. The pretreated hyperglycemic group had better preservation of PCr and ATP than the normoglycemic group.[177] Preconditioning the animal before a major hypoxic-ischemic insult may afford protection, which appears to be due to enhanced intracerebral glycogen levels,[119] increased expression of GLUT1,[141] and increased availability of alternative brain fuels.[122] The clinical question of whether glucose infusion after hypoxic-ischemic insult is of value remains controversial. Hattori and Wasterlain[139] have shown that glucose treatment after hypoxic-ischemic insult in 7-day-old rat pups protects against neuropathologic damage, but another study has shown in the same animal model a worsening in neuronal injury when glucose was given immediately after the insult.[168]

Although routine use of high-concentration glucose is not advised after a hypoxic-ischemic event in the neonate, it is clear that hypoglycemia must be avoided.

Seizures

See also Part 5 of this chapter.

Seizures occur in most infants who have sustained a significant hypoxic-ischemic insult; indeed, seizure is a feature of moderate and severe HIE. In general, the more severe or prolonged the hypoxia-ischemia, the more seizure activity the infant will have. There has been considerable debate as to whether seizure activity after a hypoxic-ischemic event confers an additional risk factor on the infant in terms of adverse neurodevelopmental outcome. If this is established, then there is an increased onus on the effective management of seizure activity. A hypoxic-ischemic insult sets in train a cascade of intraneuronal events that may result in cell death. Seizures may simply be a paraphenomenon indicating the process of neuronal demise.

Studies have shown that immature neurons are more susceptible to the development of seizures than the mature brain, but also less vulnerable to neuropathologic consequences. In animal studies, the induction of multiple short seizures over the first days of life does not result in neuronal loss, but does result in morphologic changes involving cortical activation and cell density evident when the brain was examined in adult life.[140] Furthermore, these animals exhibited impaired learning in the preweaning period[169] and lower seizure threshold in later life. Seizure activity in neonates after a hypoxic-ischemic insult usually shows a pattern of short but frequent convulsive episodes, although status epilepticus is well recognized.[118,175] There is often dissociation between clinically evident seizures and seizures recognized on EEG monitoring, so that the frequency of seizure activity after a hypoxic-ischemic insult may be underestimated by clinical observation. Therefore, asphyxiated infants are likely to have a significant seizure burden that may be underestimated by clinicians. There is evidence that although the majority of irreversible neuronal injury after recovery from hypoxic-ischemic insult is due to the underlying cause of the condition, additional functional injury may ensue secondary to the seizure burden. This strengthens the case for effective management of seizure activity following a hypoxic-ischemic event.

Fully effective anticonvulsant therapy in the neonatal period is not available at present for controlling either clinical or electrographic seizures. Phenobarbital is the mainstay of therapy, but it has been shown that although clinically evident seizures were reduced or abolished by this drug in most cases, electrographic seizures were reduced in only 4 of 14 infants after a loading dose.[118] In some infants, phenobarbital caused an increase in the duration of electrographic seizures despite a second loading dose. A study comparing the efficacy of phenobarbital against phenytoin in the management of EEG-diagnosed seizures found that in a randomized, single-blind, controlled trial there was complete seizure control in less than 50% of infants with either drug. When both drugs were given, only 50% of infants had complete seizure abolition.[159]

In a study of term asphyxiated infants, high-dose phenobarbitone (40 mg/kg) was associated with a significant reduction in severe neurodevelopmental disability. In many cases, the phenobarbital was given before the first evidence of seizure activity.[135] A meta-analysis of five studies comparing barbiturates with conventional therapy following hypoxic-ischemic encephalopathy found no difference in risk of death, or severe neurodevelopmental disability in survivors.[128] Phenobarbital has also been shown to have toxic effects on brain growth, neuronal toxicity, and adverse cognitive and behavioral effects when given to immature animals.[143] Other anticonvulsants used to treat seizures occurring after a hypoxic-ischemic insult include phenytoin (no greater efficacy than phenobarbital),[159] benzodiazepines (clonazepam, midazolam, lorazepam), lidocaine, thiopentone, sodium valproate, and lamotrigine.[143] These drugs have been evaluated in an uncontrolled manner and the information on effect is largely anecdotal.

In Europe, lidocaine is more commonly used as a second or third-line anticonvulsant, but should not be used if phenytoin has been administered because cardiotoxicity may occur. Lidocaine was effective in abolishing electroconvulsive seizures in 76% of babies who continued to seize after both phenobarbitone and midazolam treatment.[150] Midazolam infusion has also been evaluated in a group of babies who were refractory to phenobarbitone treatment for status epilepticus. Midazolam infusion abolished electroconvulsive seizures in 10 of 13 such babies.[121] It is essential that new randomized, controlled trials be started to evaluate the efficacy of the newer anticonvulsant drugs in the management of seizures due to hypoxic-ischemic insult.

There has been accumulating evidence that antiepileptic drugs have adverse effects including apoptosis, inhibition of brain growth, adverse behavioral and cognitive effects in adult life when the drugs were administered to young animals.[116]

Therapeutic management of seizures following a hypoxic-ischemic event must be pragmatic, with attempts made to stop seizure activity, either clinical or electrographic. Phenobarbital remains the first-line drug. Phenytoin is often used as a second-line anticonvulsant. Realistically, the use of both these drugs will abolish seizure activity only in a little over 50% of cases. The duration of anticonvulsant administration should be minimized to avoid the potential adverse effects of prolonged exposure. The optimal duration of anticonvulsants is unknown. Some clinicians withdraw treatment as soon as the neurologic examination normalizes.

Cerebral Edema

Cerebral edema occurs commonly after a severe hypoxic-ischemic insult and has been shown to develop at the cellular level within 1 to 2 hours of insult in a monkey model. Studies of intracranial pressure monitoring in human infants who have suffered a severe hypoxic-ischemic insult have shown that severely raised intracranial pressure (greater than 15 cm H_2O) was found in a minority of infants monitored by a median time of 26 hours.[146] In this group of asphyxiated infants with raised intracranial pressure, successful treatment of the intracranial hypertension as judged by a significant benefit on outcome, was estimated to have occurred in less than 10% of cases. There is no evidence that routine monitoring of intracranial pressure is of benefit to the infant. Raised intracranial pressure is most probably an end result of the abnormal pathophysiologic processes that occur after hypoxic-ischemic insult and in itself is a marker of damage rather than a cause of it. Consequently, the management of raised intracranial pressure becomes relatively less important.

Corticosteroids

There are few data to suggest that corticosteroids are effective in the management of hypoxia-ischemia. Animal studies on immature rat pups have shown that pretreatment with dexamethasone before a hypoxic-ischemic insult resulted in less severe injury than in untreated control animals, but treatment with dexamethasone after the insult was ineffective in ameliorating cerebral edema. Steroids are routinely used in older children and adults with focal edema, as occurs in tumor or traumatic brain injury, but appear to be much less effective after a global hypoxic-ischemic insult.

There is concern about the long-term effects of large doses of dexamethasone given shortly after birth, particularly in preterm infants, in whom it is estimated that there is a significant increase in the risk of cerebral palsy.[136] There is no scientific justification for the use of steroids after an intrapartum hypoxic-ischemic insult to treat cerebral edema.

Hypothermia

In recent years, interest in neuroprotection by brain cooling has shown benefit in both animals and humans. Studies in animal models have shown that in a variety of immature species, varying degrees of mild hypothermia (2° to 5°C) for 3 to 72 hours was effective in maintaining brain function.[172] Hypothermia has been suggested to have an effect by reducing cerebral metabolism and ATP consumption and down-regulating many intracerebral metabolic processes associated with rapid expression of early gene activation. These effects may account for the suggestion that hypothermia has a primary effect by inhibiting apoptosis.

Three major randomized controlled trials have now been published evaluating the neuroprotective role of hypothermia in the combined outcome of death and neurodevelopmental disability in mature babies.[111,132,167] All three studies shared similarities in design in that they aimed to produce hypothermia (rectal temperature of 34° to 35°C in one study[132] and 33.5°C in the other two)[111,167] for a total of 72 hours. The primary outcome in each study was death or disability at 18 months. Various differences in design of these three studies are shown in Table 40-7. The first neonatal study to be published[132] evaluated the role of selective head cooling in infants with both moderate to severe neonatal encephalopathy and abnormalities on aEEG, sufficiently severe to put the baby into a high risk of adverse outcome. The European TOBY study also used both neonatal encephalopathy and aEEG as entry criteria, but the NICHHD study[167] used only clinical criteria for entry. In regional brain cooling, a cooling cap perfused with a coolant solution at 10°C was used to reduce brain temperature and maintain a rectal temperature of 34.5°C. In total body cooling, the infant is placed on a cooling mattress or under a cooling blanket and the infant's rectal temperature reduced to 33.5°C. All babies were cooled within 6 hours of birth and maintained at a temperature of 33.5°C for 72 hours. Outcome was assessed as death or neurodevelopmental outcome at 18 months.

Despite the relative minor differences between these studies, the outcome at 18 months is remarkably consistent. All three studies showed a strong trend toward reducing death or severe disability in cooled infants, and was statistically significant in one.[167] In the selective head cooling study, a subgroup analysis showed that in babies with moderate aEEG abnormalities, there was a statistically reduced outcome for death or disability.[132] The TOBY study (Azzopardi)[111] analyzed the number of babies surviving to 18 months without neurologic abnormality and showed a statistically significant improvement in the hypothermic group (RR 1.57; 95% CI 1.16-2.12). Meta-analyses of these three studies show significantly improved survival without neurologic abnormality and significantly reduced cumulative outcome of death and severe disability (Fig. 40-70). Babies classified as moderate, rather than those with severe asphyxia, are more likely to benefit, of interest, is the apparent observation that control infants who become hyperthermic have worse outcomes.

Hypothermia appears to be a remarkably safe therapeutic maneuver within the context of randomized controlled trials. There is no reported excess of complications in the hypothermic group. Although the safety of controlled hypothermia has been shown, it is important to note that the temperature control of the hypothermic babies has been very carefully maintained within preset limits. It is clear that more severe hypothermia (<33°C) may have a detrimental effect on the baby with short-term and potentially long-term complications. Therapeutic hypothermia has been confined to studies in mature infants of no lower than 35 weeks' gestation. Historical studies have shown a vast excess of deaths in very immature babies who have become cold, and this form of treatment is not recommended in premature infants.

In regional brain cooling, it has been shown that temperature gradients through the head may affect efficacy of mild hypothermia as a neuroprotective therapy.[142] A subgroup analysis of infants enrolled into the TOBY study[111] evaluated MR brain scans in 151 infants at a median age of 8 days.[164] Infants in the hypothermia group showed a significant reduction in both basal ganglia/thalamic ($P = .03$) and white matter ($P = .016$) abnormalities, but no significant differences in cortical lesions.

OTHER NEUROPROTECTIVE STRATEGIES

The pathophysiologic process of irreversible brain injury has been reviewed earlier in this section. The processes that lead to neuronal death are complicated and incompletely understood. A number of studies have attempted to make preliminary investigations into the role of different strategies in neonatal brain protection after a hypoxic-ischemic insult, but few useful clinical data are currently available.

The calcium channel blocker nicardipine was given to four infants who had sustained severe intrapartum hypoxic-ischemic insult. In three of the four, the mean arterial blood

pressure dropped precipitously with a fall in cerebral bloodflow. The systemic effects of the relatively nonspecific calcium channel blockers significantly limit their value for brain protection.

Magnesium sulfate ($MgSO_4$) is an N-methyl-D-aspartate receptor antagonist and has been proposed to be an effective agent for brain protection. A retrospective assessment of risk factors for cerebral palsy showed that maternal exposure to $MgSO_4$ reduced the risk of this condition in their offspring,[157] but there is little evidence that the mechanism for this effect is by way of reducing the incidence of intraventricular hemorrhage in premature infants. The Collaborative Eclampsia Trial[125] reported that infants of women who had been assigned to $MgSO_4$ before delivery were significantly less likely to be intubated or admitted to a neonatal unit. A recent large multicenter study has shown no improvement in the cumulative outcome of death or cerebral palsy at 2 years, but a subgroup analysis showed a significant reduction in moderate or severe cerebral palsy in surviving infants.[163] Although studies have evaluated the role of $MgSO_4$ in term asphyxiated infants, no reports of outcome exist. $MgSO_4$ in high dose is associated with neonatal hypotension,[144] which may override any potential beneficial effect.

Allopurinol is an inhibitor of xanthine oxidase and has free radical scavenging action, but in a study involving 32 severely asphyxiated infants given allopurinol (40 mg/kg) in a randomized, double blind, placebo controlled trial there was no reduction in mortality or morbidity in infants treated with this drug.[113]

PROGNOSTIC FACTORS

Cerebral hypoxia-ischemia due to perinatal asphyxia is an important cause of neonatal mortality and morbidity. The outcome of infants sustaining cerebral hypoxia-ischemia is influenced by several factors, including the duration and severity of the insult to the brain; gestational age; presence of seizures; and associated infectious, metabolic, and traumatic derangements. Although the prognosis for any single newborn often is difficult to formulate, certain clinical and laboratory abnormalities, along with perinatal cerebral hypoxia-ischemia, are associated with a high risk of neurologic morbidity (Box 40-7).

The degree of maturity at birth is an important predictor of mortality in infants asphyxiated at birth. In a group of infants who were either stillborn or without spontaneous respirations for a minimum of 20 minutes, 32% of preterm infants survived. Of the full-term infants, 70% survived. The long-term morbidity of the survivors was 11% in the premature infants, 36% in the term infants. Nelson and Ellenberg[156] also reported an appreciably higher death rate in premature infants, but an increased risk for cerebral palsy in the full-term survivors. The lower morbidity among the premature infants was related in part to the small number of survivors in this group.

Acidosis

Obstetricians have long used blood acid-base status to ascertain the presence or absence of asphyxia in the fetus during the intrapartum period. Obstetricians concentrate on more severe degrees of acidosis and on the extent to which the altered pH reflects an underlying metabolic (lactic) acidosis. In the study of Goldaber and associates,[133] 2.5% of 3506 full-term newborns exhibited an umbilical artery pH of less than 7.00, 66.7% of whom had a metabolic component to their acidosis. Significantly more of the severely acidotic newborns exhibited low (less than 3) 1- and 5-minute Apgar scores, compared with infants with higher umbilical artery pH values. In addition, neonatal death was significantly more frequent in the severely acidotic group. Low and colleagues[148] compared 59 full-term fetuses exhibiting metabolic acidosis with 59 fetuses with normal umbilical blood acid-base status and 51 fetuses exhibiting only a respiratory acidosis at birth. Various complications, including encephalopathy, were apparent in the majority of newborns experiencing a metabolic acidosis, compared with very low complication rates in those infants with either respiratory acidosis or no acidosis at all. In addition, Low and colleagues[147] had previously demonstrated a positive correlation between the severity and duration of intrapartum metabolic acidosis and neurodevelopmental outcome at 1 year, and the same positive correlation exists for premature infants, including those weighing less than 1000 g.[131]

BOX 40–7 Predictors of Mortality and Neurologic Morbidity after Perinatal Hypoxic-Ischemic Insult

- Extended very low Apgar scores
- Time to establish spontaneous respiration
- Neonatal neurologic examination
- Brain imaging (ultrasonography, magnetic resonance imaging)
- Other investigations:
  - EEG or amplitude-integrated EEG
  - Evoked potentials (visual, brainstem auditory, and somatosensory)

Apgar Scores and Condition at Birth

Several studies have demonstrated the low sensitivity of the 1- and 5-minute Apgar scores in predicting long-term neurologic outcome. However, Nelson and associates[158] evaluated 39 full-term infants whose 20-minute Apgar scores were 3 or less. Six died in the early postnatal period, and of the 14 survivors, 8 exhibited cerebral palsy when examined at 7 years of age. Thus, the extended Apgar score is a reliable predictor of ultimate neurologic morbidity, especially when very low scores are obtained at 20 minutes. In term infants, low Apgar scores of 0 to 3 at 5 minutes was 8 times more accurate in predicting death than umbilical artery pH ≤ 7.[120]

The time from birth until onset of spontaneous, sustained respirations also has been correlated with long-term neurologic function. Mulligan and colleagues[154] reported a 19% immediate mortality rate and an 18% morbidity rate among 39 surviving full-term infants in whom spontaneous respirations did not appear for more than 1 minute after birth. D'Souza and associates[123] followed for up to 5 years 15 full-term infants who had survived apnea for 10 or more minutes at birth. Of the group, two exhibited severe neurologic deficit and five had delayed language development. Full-term infants who were apneic for 30 or more minutes were universally and severely damaged.[129] The data suggest that a prolonged delay in the initiation of spontaneous respirations is a reasonable indicator of irreversible brain damage.

Hypoxic-Ischemic Encephalopathy

Neurologic examination of the infant in the immediate newborn period provides a useful index for predicting later developmental outcome, especially in the full-term infant. Follow-up studies have shown that those infants assessed as having only mild HIE had virtually no risk of subsequent major neurodevelopmental disability, and in infants with moderate HIE approximately 75% survived without major neurologic deficit. There were very few deaths in the moderate HIE group. Infants with severe HIE had a very poor outcome, with 50% to 100% mortality rate and severe disability incidence in survivors of 65% to 75% (Table 40-8).

A numeric scoring system based on features of hypoxic-ischemic encephalopathy has been shown to be able to predict, with a high degree of accuracy, outcome at 12 months of age.[171] The maximum (worst) score was 22 and a score of 15 or more showed a positive predictive value of 92% and

*Mild and moderate considered together.
†Disability due to congenital myopathy.

negative predictive value of 82% for abnormal outcome, with a sensitivity of 71% and specificity of 96%. Using a slightly different encephalopathy score, maximal abnormal features with seizures on day 1 predicted outcome at 30 months of age correctly in 87% of cases.[152]

Very few follow-up studies are available relating to the outcome of term babies born with HIE in developing countries. Ellis and associates[127] published the 1-year outcome in 131 infants born in Kathmandu, Nepal, in 1995. Only 36% of babies born with any grade of HIE were normal at 1 year of age compared with 94% of controls and, unsurprisingly, the outcome was worse by increasing severity of HIE (74% normal for grade 1, 26% for grade 2, and 3% for grade 3). The authors calculated the total prevalence for major neurodevelopmental impairment at 1 year in this Nepalese population to be 1.1 per 1000 live births.

Hypoxic-Ischemic Encephalopathy and Less Severe Neurodisability

In recent years it has become apparent that the outcome of HIE may be more heterogeneous than was previously thought. It has been suggested that if HIE caused an infant to be damaged, then the outcome involved severe cerebral palsy with or without intellectual impairment. More recently, data have been published on less severe forms of disability in older children who have survived a perinatal hypoxic-ischemic insult at term.[134,174]

A Canadian cohort born between 1974 and 1979 was carefully assessed at the age of 8 years and compared with a control group of similar-aged children.[162] The major disability rate was comparable with that in children assessed at a younger age, but important differences at 8 years were seen in the children with HIE, but without major neurologic deficit, compared with the control subjects. The mean full-scale IQ in the control group was 112 and that of the unimpaired children who had mild HIE was 106 (not significant). For the apparently unimpaired children who had moderate HIE, the mean IQ was 102 ($P < .001$) compared with both mild HIE and control subjects. The good prognosis for cognitive and motor outcome for the infants described as having “mild fetal intrapartum asphyxia” was confirmed by another Canadian study of 43 affected children compared with a similar number of control subjects and assessed at 8 years of age.[137] There were no differences between the two groups for tests of motor and cognitive development (Bayley and McCarthy scales).

A report on the later outcome of 68 term babies with depression at birth and neonatal encephalopathy found 36% had cerebral palsy. The surviving 34 who were apparently normal were assessed at 8 years, 8 (15%) had minor neurologic dysfunction and/or perceptual motor difficulties, only 2% had only cognitive impairment, and the rest were normal. Eighty percent of the infants with minor neurologic dysfunction had an abnormality on the MR brain scan usually involving basal ganglia or white matter.[112] Similar results were reported from Norway of surviving term infants with HIE who escaped cerebral palsy but who were found to be more likely to have minor motor impairments and attention deficit hyperactivity disorder requiring additional educational support.[153]

In another cohort of term infants born between 1992 and 1994 with neonatal encephalopathy lasting more than 24 hours, 50 survivors were examined who had escaped cerebral palsy and neuropsychological testing showed lower cognitive scores mainly in the group with severe neonatal encephalopathy. This group had a mean IQ that was 11.3 points below that of the controls.[151] In particular, infants with severe neonatal encephalopathy had memory and attention/executive functions impaired compared with controls. Infants who had suffered moderate neonatal encephalopathy in the neonatal period were not significantly different from their controls in neuropsychological testing but they were identified as having a greater need for special educational in school.

In summary, the prognosis for children with HIE depends on the severity and duration of the neurologic abnormality. Major neurodevelopmental problems occur only after moderate and severe HIE, and death is a significant risk in severe HIE. Emerging data strongly support the observations that a significant number of children with perinatal hypoxic-ischemic insult, previously considered to be without major problems, have significant perceptual-motor difficulties or a reduction in cognitive abilities. The predictive values of neuroimaging procedures and other investigative techniques are described earlier. MRI and EEG assessment provides the basis for the most accurate prediction of disability in later childhood.

PART 5

Seizures in Neonates

Mark S. Scher

Neonatal seizures are one of the few neonatal neurologic conditions that require immediate medical attention. Although prompt diagnostic and therapeutic plans are needed, multiple challenges impede the physician's evaluation of the newborn with suspected seizures (Box 40-8). Clinical and electroencephalographic (EEG) manifestations of neonatal seizures vary dramatically from those in older children, and recognition of the seizure state remains the foremost challenge. This dilemma is underscored by the brevity and subtlety of the clinical repertoire of the neonatal neurologic examination. Environmental restrictions of the sick infant in an intensive care setting, who may be confined to an incubator, intubated, and attached to multiple catheters, limit accessibility. Medications alter arousal and muscle tone and limit the clinician's ability to distinguish clinical neurologic signs reflective of the underlying disease state. Brain injury from antepartum factors may precipitate neonatal seizures as part of an encephalopathic clinical picture during the intrapartum and neonatal periods, well beyond when brain injury occurred. Overlapping medical conditions from fetal through neonatal periods must be factored into the most appropriate etiologic algorithm to explain seizure expression before applying the most accurate prognosis. Medication options to treat seizures effectively remain elusive and may need to be applied on a specific etiologic basis. Potential neuroresuscitative strategies proposed for the encephalopathic neonate with seizures must consider maternal, placental/cord, and fetal disease conditions that cause or contribute to neonatal seizure expression and potential brain injury as part of both fetal and neonatal brain disorders of varying etiologies.

BOX 40–8 Dilemmas Regarding Neonatal Seizures

Diagnostic choices
  - Reliance on clinical versus electroencephalographic criteria

Etiologic explanations
  - Multiple prenatal/neonatal conditions as a function of time

Treatment decisions
  - Who, when, how, and for how long?

Prognostic questions
  - Mechanisms of injury based on etiologies versus intrinsic vulnerability of the immature brain to prolonged seizures

DIAGNOSIS: CLINICAL VERSUS ELECTROENCEPHALOGRAPHIC

Neonatal seizures are usually brief and subtle in clinical appearance, sometimes comprising unusual behaviors that are difficult to recognize and classify. Medical personnel vary significantly in their ability to recognize suspect behaviors, contributing to both overdiagnosis and underdiagnosis. The most common practice has been to classify clinical behaviors as seizures without EEG confirmation. However, abnormal motor or autonomic behaviors may represent age- and state-specific behaviors in healthy infants, or nonepileptic paroxysmal conditions in symptomatic infants. For these reasons, confirmation of suspect clinical events with coincident EEG recordings is now more widely recommended. Although in patients with few seizures, these may be missed as brief random events on routine EEG studies, synchronized video/EEG/polygraphic recordings potentially establish more reliable start points and endpoints for electrically confirmed seizures that require consideration for treatment intervention.[10] Rigorous physiologic monitoring also better integrates the diagnosis of the seizure state with etiologic, treatment, and prognostic considerations.

Clinical Seizure Criteria

Neonatal seizures are listed separately from the traditional classification of seizures and epilepsy during childhood. The International League Against Epilepsy's Classification adopted by the World Health Organization still places neonatal seizures in an unclassified category. Another classification scheme suggests a strict distinction of clinical seizure (nonepileptic) events from electrographically confirmed (epileptic) seizures with respect to possible treatment interventions.[55] Continued refinement of such novel classifications is needed to reconcile the variable agreement between clinical and EEG criteria for establishing a seizure diagnosis[7,96] in the context of nonepileptic movement disorders caused by acquired diseases, malformations, or medications.

Several caveats (Box 40-9) may be useful in the identification of suspected neonatal seizures, yet continue to raise questions regarding our diagnostic acumen.

The clinical criteria for neonatal seizure diagnosis were historically subdivided into five clinical categories: focal clonic, multifocal or migratory clonic, tonic, myoclonic, and

BOX 40–9 Caveats Concerning Recognition of Neonatal Seizures

- Specific stereotypic behaviors occur in association with normal neonatal sleep or waking states, medication effects, and gestational maturity.
- Any abnormal repetitive activity may be a clinical seizure if out of context for expected neonatal behavior.
- Attempt to document coincident electrographic seizures with the suspected clinical event.
- Abnormal behavioral phenomena may have inconsistent relationships with coincident electroencephalographic seizures, suggesting a subcortical seizure focus.
- Nonepileptic pathologic movement disorders are events that are independent of the seizure state and may also be expressed by neonates.

subtle seizures.[93] A subsequent classification expands the clinical subtypes, adopting a strict temporal occurrence of specific clinical events with coincident electrographic seizures to distinguish neonatal clinical “nonepileptic” seizures from “epileptic” seizures (Box 40-10).[55]

BOX 40–10 Classification of Neonatal Seizures Based on Electroclinical Findings

CLINICAL SEIZURES WITH A CONSISTENT ELECTROCORTICAL SIGNATURE (PATHOPHYSIOLOGY: EPILEPTIC)

Focal clonic

- Unifocal
- Multifocal
- Hemiconvulsive
- Axial

Focal tonic

- Asymmetric truncal posturing
- Limb posturing
- Sustained eye deviation

Myoclonic

- Generalized
- Focal
- Spasms

Flexor

- Extensor
- Mixed extensor/flexor

CLINICAL SEIZURES WITHOUT A CONSISTENT ELECTROCORTICAL SIGNATURE (PATHOPHYSIOLOGY: PRESUMED NONEPILEPTIC)

Myoclonic

- Generalized
- Focal
- Fragmentary

Generalized tonic

- Flexor
- Extensor
- Mixed extensor/flexor

Motor automatisms

- Oral-buccal-lingual movements
- Ocular signs
- Progression movements
- Complex purposeless movements

ELECTRICAL SEIZURES WITHOUT CLINICAL SEIZURE ACTIVITY

From Mizrahi EM, Kellaway P: *Diagnosis and management of neonatal seizures*, Philadelphia, 1998, Lippincott-Raven.

SUBTLE SEIZURE ACTIVITY

Subtle seizure activity is the most frequently observed category of neonatal seizures and includes repetitive buccolingual movements, orbital-ocular movements, unusual bicycling or peddling, and autonomic findings (Fig. 40-71A). Any subtle paroxysmal event that interrupts the expected behavioral repertoire of the newborn infant and appears stereotypical or repetitive should heighten the clinician’s level of suspicion for seizures. However, alterations in cardiorespiratory regularity, body movements, and other behaviors during active (rapid eye movement [REM]) sleep, quiet (non-REM) sleep, or waking segments must be recognized before proceeding to a seizure evaluation.[74] Within the subtle category of neonatal seizures are stereotypical changes in heart rate, blood pressure, oxygenation, or other autonomic signs, particularly during pharmacologic paralysis for ventilatory care. Other unusual autonomic events include penile erections, skin changes, salivation, and tearing. Autonomic expressions may be intermixed with motor findings. Isolated autonomic signs such as apnea, unless accompanied by other clinical findings, are rarely associated with coincident electrographic seizures[16] (see Fig. 40-71B). Because subtle seizures are both clinically difficult to detect and only variably coincident with EEG seizures, synchronized video/EEG/polygraphic recordings are recommended to document temporal relationships between clinical behaviors and coincident electrographic events.[8,10,55] Despite the “subtle” expression of this seizure category, these children may have suffered significant brain injury.

CLONIC SEIZURES

Rhythmic movements of muscle groups in a focal distribution that consist of a rapid phase followed by a slow return movement are clonic seizures, to be distinguished from the symmetric “to-and-fro” movements of tremulousness or jitteriness. Gentle flexion of the affected body part easily suppresses the tremor, whereas clonic seizures persist. Clonic movements can involve any body part such as the face, arm, leg, and even diaphragmatic or pharyngeal muscles. Generalized clonic activities can occur in the newborn but rarely consist of a classic tonic followed by clonic phase, which is characteristic of the generalized motor seizure noted in older children and adults. Focal clonic and hemiclonic seizures have been described with localized brain injury, usually from cerebrovascular lesions,[10] but can also be seen with generalized brain abnormalities. As in older patients, focal seizures in the

Figure 40–71. A, Electroencephalogram (EEG) segment of a 40-week gestation, 1-day-old girl after severe asphyxia resulting from rupture of velamentous insertion of the umbilical cord during delivery. An electrical seizure in the right central/midline region is recorded *(arrows)*, coincident with buccolingual and eye movements (see comments and eye channels on record). B, Synchronized video/EEG record of a 35-week gestation, 1-day-old girl with *Escherichia coli* meningitis and cerebral abscesses. The *top arrow* notes apnea coincident with prominent right hemispheric and midline electrographic seizures *(middle and bottom arrows)*. In addition to apnea, other motor signs coincident to EEG seizures were noted at other times during the record. (***A**, From Scher MS, Painter MJ: Electrographic diagnosis of neonatal seizures: issues of diagnostic accuracy, clinical correlation and survival. In Wasterlain CG, Vert P, editors:* Neonatal seizures, *New York, 1990, Raven Press, p. 17, with permission;* ***B**, From Scher MS, Painter MJ: Controversies concerning neonatal seizures,* Pediatr Clin North Am *36:288, 1989, with permission.)*

neonate may be followed by transient motor weakness, historically referred to as a *transient Todd paresis* or *paralysis*, to be distinguished from a more persistent hemiparesis over days to weeks. Clonic movements without EEG-confirmed seizures have been described in neonates with normal EEG backgrounds, and their neurodevelopmental outcome can be normal.[8]

MULTIFOCAL (FRAGMENTARY) CLONIC SEIZURES

Multifocal or migratory clonic activities spread over body parts either in a random or anatomically appropriate fashion. Such seizure movements may alternate from side to side and appear asynchronously between the two halves of the child's body. The word *fragmentary* was historically applied to distinguish this event from the more classic, generalized tonic-clonic seizure seen in the older child. Multifocal clonic seizures may also resemble myoclonic seizures, consisting of brief, shocklike muscle twitching of the midline or extremity musculature. Neonates with this seizure description either die or suffer significant neurologic morbidity.[70]

TONIC SEIZURES

Tonic seizures refer to a sustained flexion or extension of axial or appendicular muscle groups. Tonic movements of a limb or sustained head or eye turning may also be noted. Tonic activity with coincident EEG needs to be carefully documented because 30% of such movements lack a temporal correlation with electrographic seizures (Fig. 40-72). "Brainstem release" resulting from functional decortication after severe neocortical dysfunction or damage is one physiologic explanation for this nonepileptic activity (discussed later). Extensive neocortical damage or dysfunction permits the emergence of uninhibited subcortical expressions of extensor movements.[72] Tonic seizures may also be misidentified when the nonepileptic movement disorder of dystonia is the more appropriate behavioral description. Both tonic movements and dystonic posturing may also simultaneously occur.

MYOCLONIC SEIZURES

Myoclonic movements are rapid, isolated jerks that can be generalized, multifocal, or focal in an axial or appendicular distribution. Myoclonus lacks the slow return phase of the clonic movement complex described previously. Healthy preterm infants commonly exhibit myoclonic movements without seizures or a brain disorder. EEG therefore is recommended to confirm the coincident appearance of electrographic discharges with these movements (Fig. 40-73). Pathologic myoclonus in the absence of EEG seizures also can occur in severely ill preterm or full-term infants after severe brain dysfunction or damage.[78] As with older children and adults, myoclonus may reflect injury at multiple levels of the neuraxis from the spine, brainstem, and to cortical regions. Stimulus-evoked myoclonus with either coincident single spike discharges or sustained electrographic seizures have been reported.[79] An extensive evaluation must be initiated to exclude metabolic, structural, and genetic causes. Rarely, healthy sleeping neonates exhibit abundant myoclonus that subsides with arousal to the waking state,[15] termed *benign sleep myoclonus of the newborn.*

Nonepileptic Behaviors of Neonates

Specific nonepileptic neonatal movement repertoires continually challenge the physician's attempt to reach an accurate diagnosis of seizures and avoid the unnecessary use of antiepileptic medications. Coincident paper or synchronized video/EEG/polygraphic recordings are now the suggested diagnostic tool to confirm the temporal relationship between the suspect clinical phenomena and electrographic expression of seizures. The following three examples of nonepileptic movement disorders incorporate a classification scheme,[55] based on the absence of coincident EEG seizures.

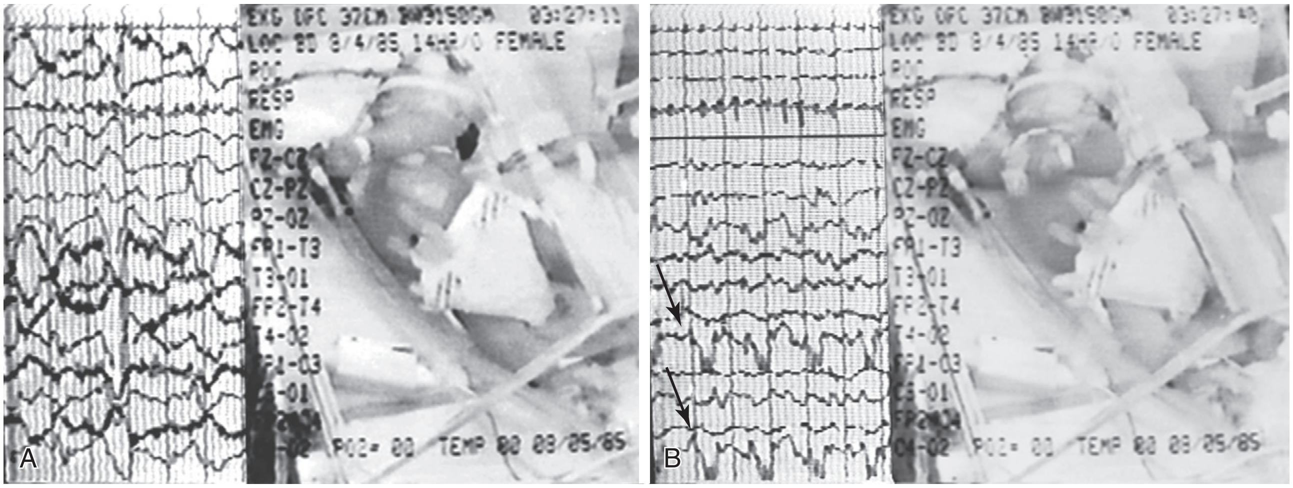

Figure 40–72. **A**, Segment of a synchronized video/electroencephalogram (EEG) record of a 37-week gestation, 1-day-old girl who suffered asphyxia, demonstrating prominent opisthotonos with left arm extension in the absence of coincident electrographic seizure activity. **B**, Synchronized video/EEG record of the same patient as in **A**, documenting electrographic seizure in the right posterior quadrant *(arrows)*, after cessation of left arm tonic movements and persistent opisthotonos. *(From Scher MS, Painter MJ: Controversies concerning neonatal seizures,* Pediatr Clin North Am *36:292, 1989, with permission.)*

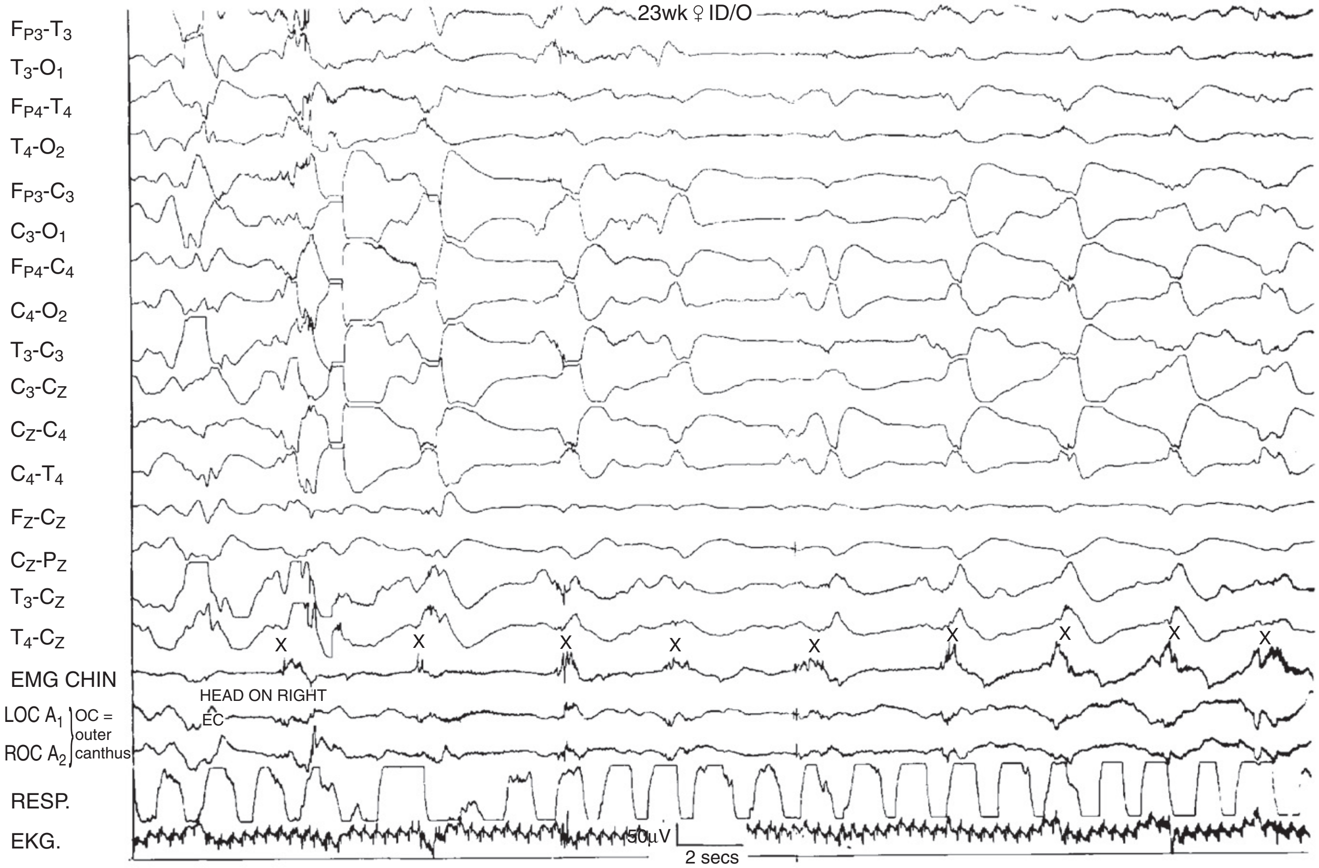

Figure 40–73. Electroencephalogram segment of a 23-week gestation, 1-day-old girl with grade III intraventricular hemorrhage and progressive ventriculomegaly. An electroclinical seizure is noted with coincident myoclonic movements of the diaphragm ("x" marks). *(From Scher MS: Pathological myoclonus of the newborn: electrographic and clinical correlations,* Pediatr Neurol *1:342, 1985, with permission.)*

TREMULOUSNESS OR JITTERINESS WITHOUT ELECTROGRAPHIC CORRELATES

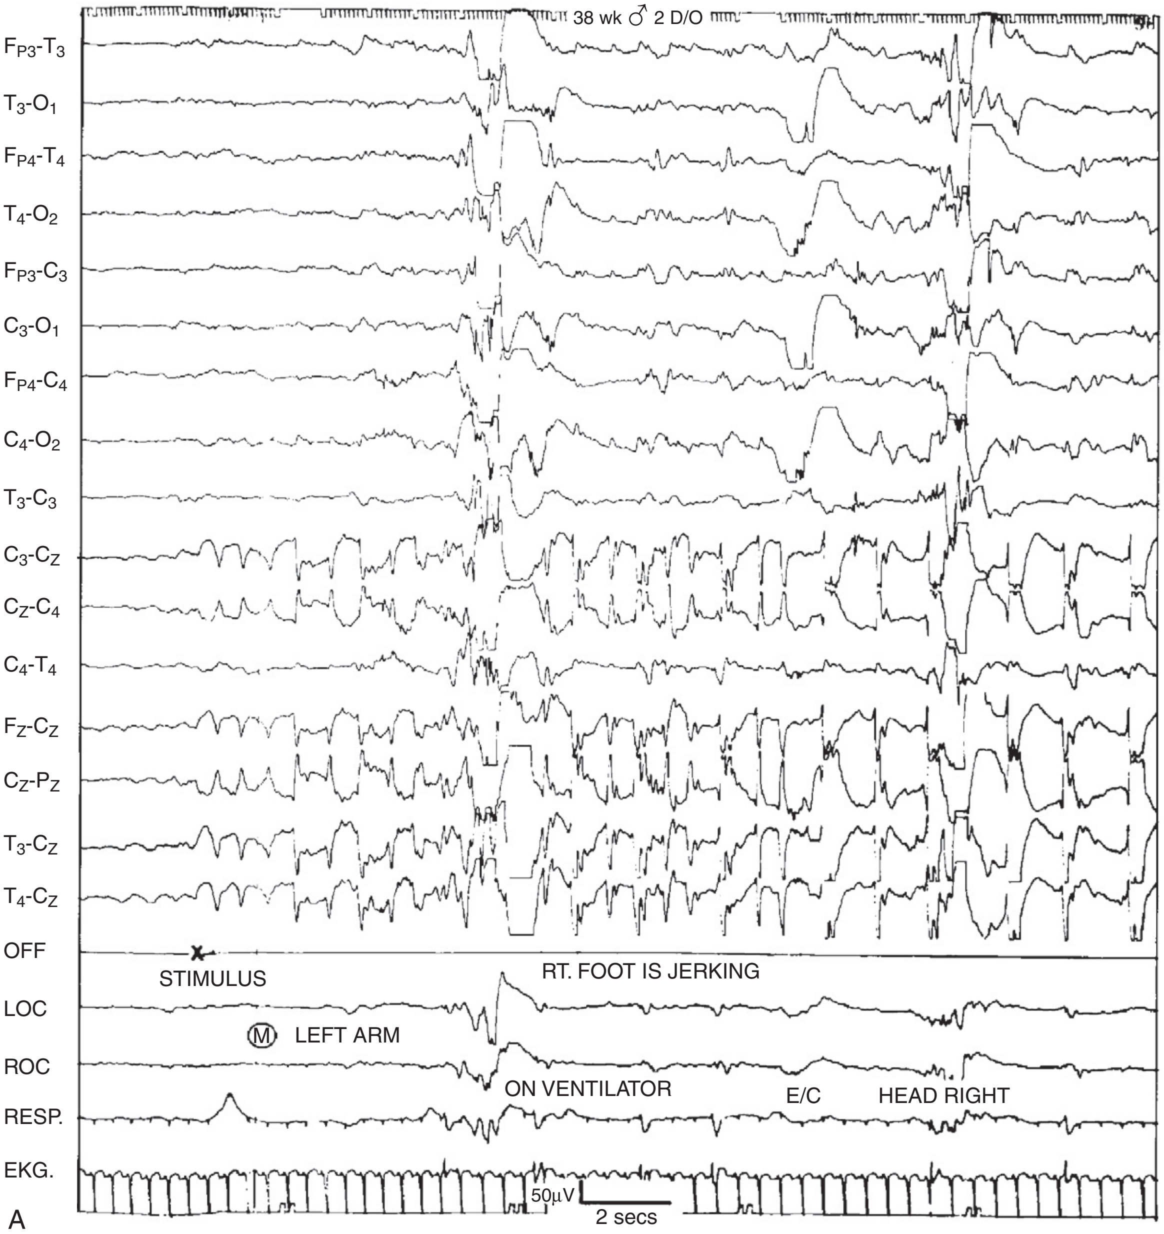
Tremors are frequently misidentified as clonic activity. Unlike the unequal phases of clonic movements described earlier, the flexion and extension phases of tremor are equal in amplitude. Children are usually alert or hyperalert but may also appear somnolent. Passive flexion and repositioning of the affected tremulous body part diminishes or eliminates the movement. Such movements are usually spontaneous but can be provoked by tactile stimulation. Metabolic or toxin-induced encephalopathies, including mild asphyxia, drug withdrawal, hypoglycemia, hypocalcemia, intracranial hemorrhage, hypothermia, and growth restriction, are common clinical scenarios when such movements occur. Neonatal tremors usually decrease with age; for example, in 38 full-term infants, excessive tremulousness resolved spontaneously over a 6-week period, with 92% being neurologically normal at 3 years of age.[88] Medications are rarely considered to treat this particular movement disorder.[63]

NEONATAL MYOCLONUS WITHOUT ELECTROGRAPHIC SEIZURES

Myoclonic movements are either (1) bilateral and synchronous or (2) asymmetric and asynchronous. Clusters of myoclonic activity occur predominantly during active (REM) sleep, more so in the preterm infant,[24] but also in healthy term infants. These benign movements are not stimulus sensitive and have no coincident electrographic seizure activity or changes in EEG background rhythms. When this movement occurs in the healthy term neonate, it is usually suppressed during wakefulness. This clinical entity of benign neonatal sleep myoclonus is a diagnosis of exclusion after an extensive consideration of pathologic diagnoses.[15]

Some infants with severe central nervous system dysfunction present with nonepileptic spontaneous or stimulus-evoked myoclonus. Metabolic encephalopathies (e.g., glycine encephalopathy), cerebrovascular lesions, brain infections, or congenital malformations may present with nonepileptic myoclonus.[78] Encephalopathic neonates may respond to tactile or painful stimulation by either isolated focal, segmental, or generalized myoclonic movements. Rarely, cortically generated spike or sharp-wave discharges as well as seizures may also be noted on the EEG coincident with these myoclonic movements[78] (Fig. 40-74). Medication-induced myoclonus as well as stereotypic movements have also been described.[85]

A rare familial disorder has been described in the neonatal and early infancy periods, termed *hyperekplexia*. These movements usually are misinterpreted as a hyperactive startle reflex. These infants are stiff with severe hypertonia, which may lead to apnea and bradycardia. Forced flexion of the



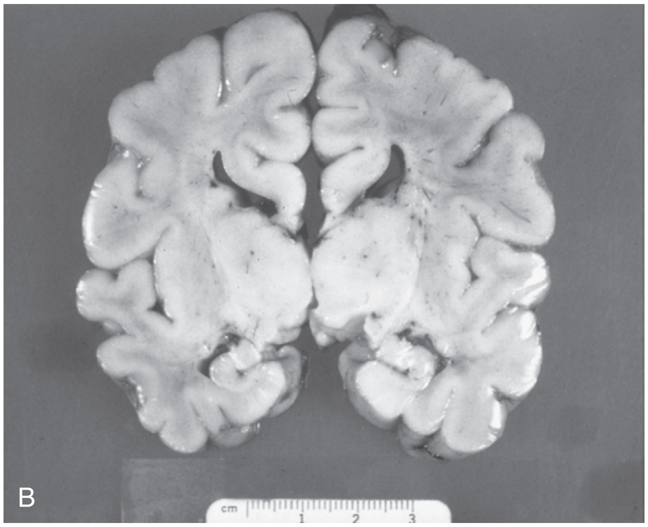


Figure 40–74. **A**, Segment of an electroencephalographic recording of a 38-week gestation, 2-day-old boy with glycine encephalopathy who has stimulus-sensitive generalized and multifocal myoclonus. Note the onset of a midline (C_z onset) electrographic seizure with a painful stimulus, followed by right foot myoclonus. **B**, Coronal section of the brain for the patient described in **A**, with agenesis of the corpus callosum and bat-wing shape of lateral ventricles. Spongy myelinosis was noted on microscopic examination. *(From Scher MS: Pathological myoclonus of the newborn: electrographic and clinical correlations,* Pediatr Neurol *1:342, 1985, with permission.)*

neck or hips sometimes alleviates these events. EEG background is generally age appropriate. The postulated defect of these individuals pertains to regulation of brainstem centers facilitating myoclonic movements. Occasionally, benzodiazepines or valproic acid lessen the startling, stiffening, or falling events. Neurologic prognosis is variable.

NEONATAL DYSTONIA/DYSKINESIA WITHOUT ELECTROGRAPHIC SEIZURES

Dystonia or dyskinesia is a third commonly misdiagnosed movement disorder that is often misrepresented as tonic or subtle seizures, or may be expressed with nonepileptic tonic movements. These movements can be associated with either acute or chronic disease states involving basal ganglia structures or extrapyramidal pathways, commonly injured after antepartum or intrapartum severe asphyxia (termed *status marmoratus*),[93] or rarely with specific inherited metabolic diseases[46] or drug toxicity from neuropsychiatric medications given to the mother. Alternatively, posturing reflects subcortical motor pathways that remain functionally unopposed because of a diseased or malformed neocortex.[72]

Electrographic Seizure Criteria

Electrographic/polysomnographic studies have become invaluable tools for the assessment of suspected seizures.[10,12,55,67,95] Technical and interpretative skills of normal and abnormal neonatal EEG sleep patterns must be mastered before the clinician develops a confident visual analysis style for seizure recognition.[66,74]

Corroboration with the EEG technologist is always an essential part of the diagnostic process because physiologic and nonphysiologic artifacts can masquerade as EEG seizures. The physician must always anticipate expected behaviors for the child for a specific gestational maturity, medication use, and state of arousal in the context of potential artifacts.

For the epileptic older child and adult, it is generally accepted that the epileptic seizure is a clinical paroxysm of altered brain function with the simultaneous presence of an electrographic event on an EEG recording. Some advocate the use of single-channel computerized devices for prolonged monitoring given the multiple logistical problems using conventional multichannel recording devices. This device, however, may not detect focal or regional seizures because recording from a single channel will not detect localized disease processes distant from the channel.[67]

Epilepsy monitoring services for older children and adults readily use intracerebral or surface electrocorticography to detect seizures. Such recording strategies, however, are not ethically appropriate or practical for the neonatal patient. Subcortical foci therefore are difficult to eliminate definitively from consideration (see later).

ICTAL ELECTROENCEPHALOGRAPHIC PATTERNS—A MORE RELIABLE MARKER FOR SEIZURE ONSET, DURATION, AND SEVERITY

Neonatal EEG seizure patterns commonly consist of a repetitive sequence of waveforms that evolve in frequency, amplitude, electrical field, and morphology. Four types of ictal patterns have been described: focal ictal patterns with normal background, focal patterns with abnormal background, multifocal ictal patterns, and focal monorhythmic periodic patterns of various frequencies. It is generally suggested that a minimal duration of 10 seconds with the evolution of discharges is required to distinguish electrographic seizures from repetitive but nonictal epileptiform discharges.[10,13] Clinical neurophysiologists usually classify brief or prolonged repetitive discharges with a lack of evolution as nonictal patterns, but some argue that simply the presence of epileptiform discharges is confirmatory of seizures.[86] The specific features of electrographic seizure duration and topography are unique to the neonatal period.

SEIZURE DURATION AND TOPOGRAPHY

Few studies have quantified minimal or maximal seizure durations in neonates.[9,13,81] Most notably, the definition of the most severe expression of seizures that potentially promotes brain injury, status epilepticus, can be problematic. For the older patient, status epilepticus is defined as at least 30 minutes of continuous seizures or two consecutive seizures with an interictal period during which the patient fails to return to full consciousness. This definition is not easily applied to the neonate for whom the level of arousal may be difficult to assess, particularly if sedatives are given. One study arbitrarily defined neonatal status epilepticus as continuous seizure activity for at least 30 minutes, or 50% of the recording time[81]; 33% (11 of 34 term infants) had status epilepticus with a mean duration of 29.6 minutes before antiepileptic drug use, and another 9% (3 of 34 preterm infants) also had status epilepticus with an average duration of 5.2 minutes per seizure (i.e., 50% of the recording time). The mean seizure duration was longer in the full-term infant (i.e., 5 minutes) compared with the preterm infant (i.e., 2.7 minutes). Given that more than 20% of this study group fit the criteria for status epilepticus based on EEG documentation, concerns must be raised regarding the underdiagnosis of the more severe form of seizures that potentially contribute to brain injury.

Uncoupling of the clinical and electrographic expressions of neonatal seizures after antiepileptic medication administration also contributes to an underestimation of the true seizure duration, including status epilepticus (Fig. 40-75). One study estimated that 25% of neonates expressed persistent electrographic seizures despite resolution of their clinical seizure behaviors after receiving antiepileptic medications,[80] termed *electroclinical uncoupling*. Other pathophysiologic mechanisms besides medication effect also might explain uncoupling.[7]

Most neonatal electrographic seizures arise focally from one brain region. Generalized synchronous and symmetric repetitive discharges can also occur. In one study, 56% of seizures were seen in a single location at onset; specific sites included temporal-occipital (15%), temporal-central (15%), central (10%), frontotemporal-central (6%), frontotemporal (5%), and vertex (5%). Multiple locations at the onset of the electrographic seizures were noted in 44%.[10] Electrographic discharges may be expressed as specific EEG frequency ranges from fast to slow, including beta, alpha, theta, or delta activities. Multiple electrographic seizures can also be expressed independently in anatomically unrelated brain regions.

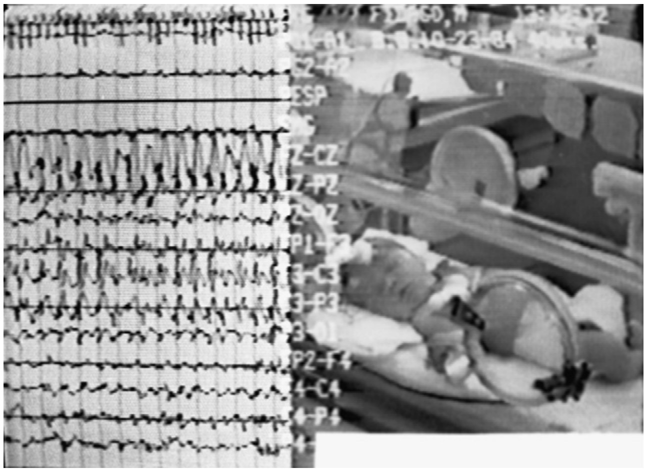

Figure 40–75. Segment of a synchronized video/electroencephalogram of a 40-week gestation, 1-day-old boy with electrographic status epilepticus noted in the left central/midline regions, after antiepileptic medication administration. Focal right shoulder clonic activity was noted only intermittently, whereas continuous electrographic seizures were documented mostly without clinical expression. This phenomenon of uncoupling of electrical and clinical seizure activity is associated with antiepileptic drug administration (see text). *(From Scher MS, Painter MJ: Controversies concerning neonatal seizures,* Pediatr Clin North Am *36:290, 1989, with permission.)*

At the opposite end of the spectrum from periodic discharges, brief rhythmic discharges that are less than 10 seconds in duration have also been addressed with respect to an association with seizures and outcome (Fig. 40-76). Neonates with electrographic seizures may also exhibit these brief discharges; other neonates express only isolated discharges without seizures. Neonates with brief discharges can suffer from hypoglycemia or periventricular leukomalacia, which carries a higher risk for neurodevelopmental delay.[58]

Brainstem Release Phenomena

Based on 415 clinical seizures in 71 infants, clonic seizure activity had the best correlation with coincident electrographic seizures. "Subtle" clinical events, on the other hand, had a more inconsistent relationship with coincident EEG seizure activity, suggesting nonepileptic brainstem release phenomena for at least a proportion of such events. Functional decortication resulting from neocortical damage without coincident EEG seizures has therefore been suggested, such as with tonic posturing, as illustrated in Figure 40-72A. Newborns with nonseizure brainstem release activity may express a different functional pattern of metabolic dysfunction, detected as altered glucose uptake on single-photon emission computed tomography studies, than neonates with seizures.[3] A suggestion to document increased prolactin levels with clinical seizures has also been reported,[33] but such levels have not yet been correlated with electrographic seizures.

Subcortical Seizures and Electroclinical Dissociation

Experimental studies on immature animals also support the possibility that subcortical structures may initiate seizures, which subsequently, although intermittently, propagate to the cortical surface. Although EEG depth recordings in adults and adolescents help document subcortical seizures both with and without clinical expression, this technology is not applicable or appropriate to the neonate.

Electroclinical dissociation is one proposed mechanism by which subcortical seizures may appear only intermittently on surface-recorded EEG studies.[96] Electroclinical dissociation has been defined as a reproducible clinical event that occurs both with and without coincidental electrographic seizures. In one group of 51 infants with electroclinical seizures, 33 infants simultaneously expressed both electrical and clinical seizure phenomena. Extremity movements were more significantly associated with synchronized electroclinical seizures. However, a subset of 18 of 51 neonates (35%) also expressed electroclinical dissociation on EEG recordings. For neonates who expressed electroclinical dissociation, the clinical seizure component always preceded the electrographic seizure expression, suggesting that a subcortical focus initiated the seizure state. Some of these children also expressed synchronized electroclinical seizures, even on the same EEG record. EEG clearly is required to document the electrographic phase after the initial behavioral event.

Controversy remains over whether subcortical seizures versus nonictal functional decortication best categorizes suspect clinical behaviors without coincident EEG documentation. This dilemma should encourage the clinician to use the EEG as a neurophysiologic yardstick by which more exact seizure start points and endpoints can be assigned, before offering pharmacologic treatment with antiepileptic drugs. Neonates certainly exhibit electrographic seizures that go undetected unless EEG is used.[59] This is best shown in neonates who are pharmacologically paralyzed for ventilatory assistance, or in infants with clinical seizures that are suppressed by the use of antiepileptic drugs.[10,75,80] In one cohort of 92 infants, 60% of whom were pretreated with antiepileptic medications, 50% of neonates had electrographic seizures with no clinical accompaniment.[80] Both clinical and electrographic seizure criteria were noted for 45% of 62 preterm and 53% of 33 full-term infants. Seventeen infants were pharmacologically paralyzed when the EEG seizure was first documented. A later cohort of 60 infants, none of whom were pretreated with antiepileptic medications, included 7% with only electrographic seizures before antiepileptic drug administration,[80] and 25% who expressed electroclinical uncoupling after antiepileptic drug use.

Incidence of Neonatal Seizures

Overestimation and underestimation of neonatal seizures are consequentially reported whether clinical or electrical criteria are used. Using clinical criteria, seizure incidences ranged from 0.5% in term infants to 22.2% in preterm neonates.[69] Discrepancies in incidence reflect not only varying postconceptional ages of the study populations chosen, but also poor interobserver reliability[35] and the hospital setting in which

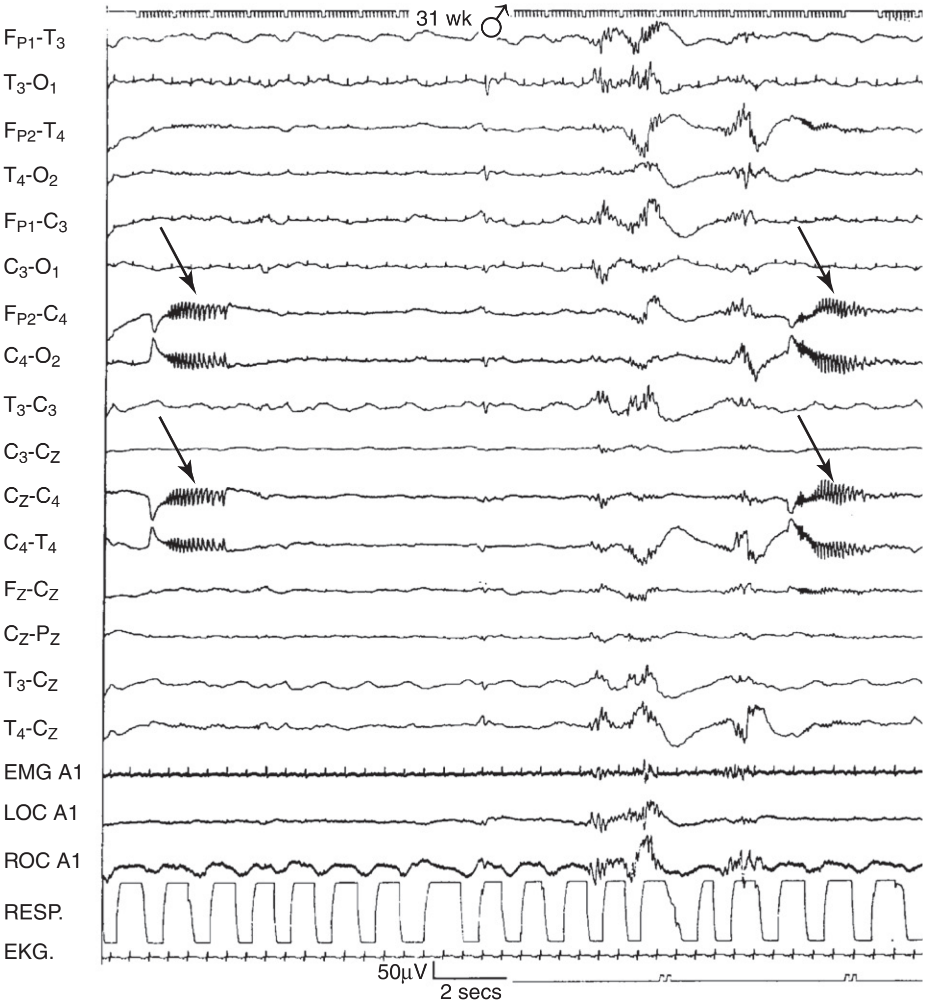

Figure 40–76. Electroencephalogram segment of a boy at 31 weeks' gestational age with repetitive brief epileptiform discharges in the right central region *(arrows)* that are less than 10 seconds in duration and do not qualify as an electrographic seizure.

the diagnosis was made. Hospital-based studies that include high-risk deliveries generally report a higher seizure incidence. Population studies[34] that include less medically ill infants from general nurseries report lower percentages. Incidence figures based only on clinical criteria without EEG confirmation include "false-positive" results, consisting of the neonates with either normal or nonepileptic pathologic neonatal behaviors. Conversely, the absence of scalp-generated EEG seizures may include a subset of "false-negative" results from subjects who express seizures only from subcortical brain regions without expression on the cortical surface. Consensus between those relying on clinical and EEG criteria is still required.

Interictal Electroencephalographic Pattern Abnormalities

Interictal EEG abnormalities (including nonictal repetitive epileptiform discharges) have important prognostic implications for both preterm and full-term infants. Severely abnormal bihemispheric patterns include the burst suppression pattern (Fig. 40-77), electrocerebral inactivity, low-voltage invariant pattern, persistently slow background pattern, multifocal sharp waves, and marked asynchrony.[9] For infants with hypoxic-ischemic encephalopathy (HIE), subclassifications of specific EEG patterns such as burst suppression with or without reactivity may give a more accurate prediction of outcome.[89] Dysmaturity of the EEG sleep background for child's corrected age has also been an important feature to recognize; discordance between cerebral and noncerebral components of sleep state or immaturity of EEG patterns for the given postconceptional age of the infant predict a higher risk for neurologic sequelae.[75,76,93] Even focal or regional patterns have prognostic significance, such as with preterm infants who express repetitive positive sharp waves at the midline or central regions often noted with intraventricular hemorrhage and periventricular leukomalacia.[74]

Screening infants at risk for neonatal seizures with a routine EEG soon after birth allows identification of more severe interictal EEG background abnormalities that more likely predict seizure occurrence on subsequent neonatal records.[36]

Interictal EEG findings are not pathognomonic for particular etiologies, pathophysiologic mechanisms, or timing.[75] History, physical examination, and laboratory findings need to be integrated with the electrographic interpretation of both ictal and interictal pattern abnormalities for the particular child. Serial EEG studies better assist the clinician in diagnostic and prognostic interpretations.[91] As with abnormal examination findings into the second week of life, the persistence of electrographic abnormalities also raises prognostic concerns. For

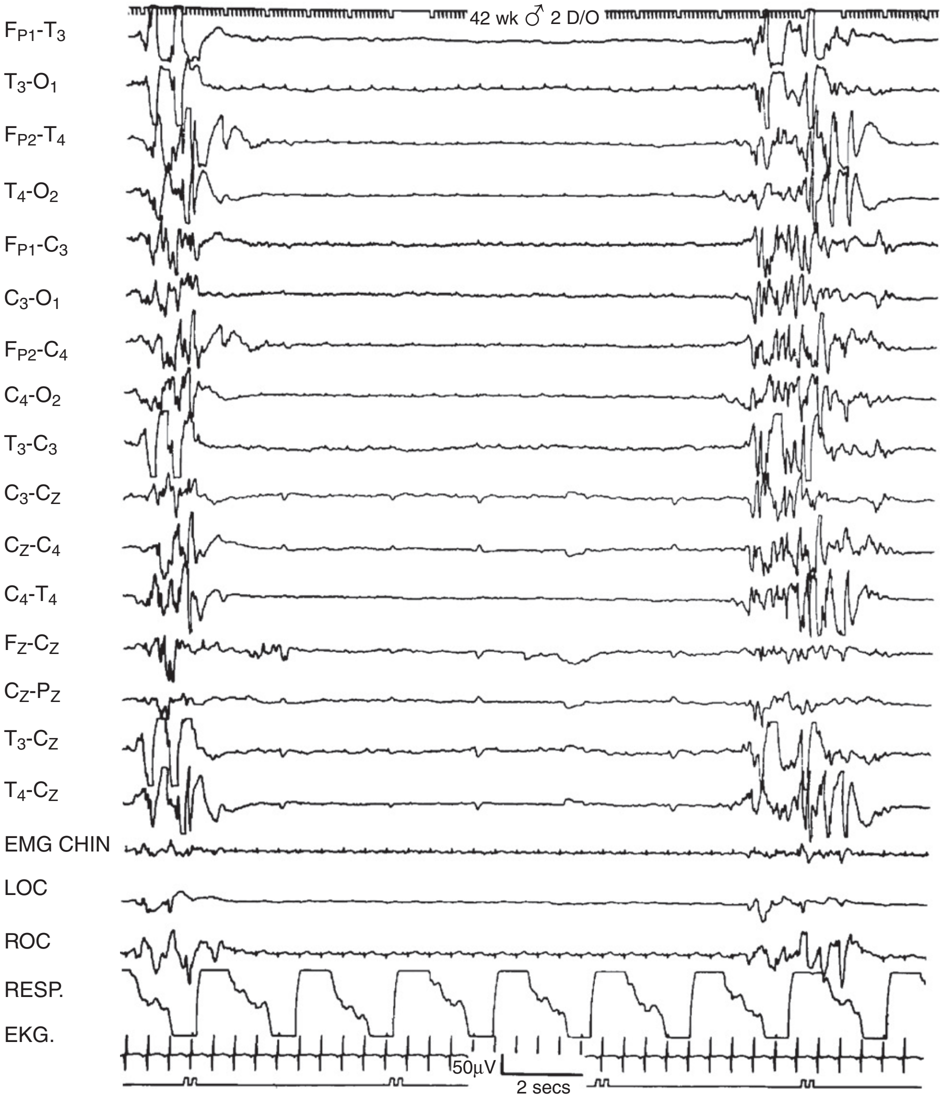

Figure 40–77. Electroencephalogram (EEG) segment of a 42-week gestation, 2-day-old boy expressing a severe interictal EEG background abnormality termed a burst suppression or paroxysmal pattern.

example, the newborn who expresses severe EEG abnormalities into the second week of life implies a greater likelihood for neurologic impairment, even despite the resolution of clinical dysfunction. Conversely, the child who rapidly recovers from a significant brain disorder, with the reemergence of normal EEG features during the first few days after birth, may experience comparatively fewer neurologic sequelae. Interictal EEG pattern abnormalities also reflect fetal brain disorders that preceded labor and delivery. The depth and severity of the neonatal brain disorder (defined by clinical and electrographic criteria) therefore may reflect chronic injury to the fetus who subsequently becomes symptomatic after a stressful intrapartum period, with or without more recent injury. (See also Part 4 of this chapter.)

MAJOR ETIOLOGIES FOR SEIZURES

Asphyxia-Related Events

See also Part 4.

Neonatal seizures are not disease specific and can be associated with a variety of medical conditions that occur before, during, or after parturition. Seizures may occur as part of an asphyxial brain disorder that is expressed after birth (termed *HIE from intrapartum stress*), or alternatively can occur as part of a more nonspecific neonatal encephalopathy from etiologies other than intrapartum asphyxia.[1,41] Importantly, neonatal seizures can also present as an isolated clinical sign from a remote antepartum disease or injury without other signs of a postnatal encephalopathy. A logistic model to predict seizures emphasizes the accumulation of both antepartum and intrapartum factors to increase the likelihood of neonatal seizure occurrence.[64] Although separately these factors had low positive predictive values, a significant cumulative risk profile included antepartum maternal anemia, bleeding, asthma, meconium-stained amniotic fluid, abnormal fetal presentation, fetal distress, and shoulder dystocia.

Hypoxia-ischemia (i.e., asphyxia) is traditionally considered the most common causal factor associated with neonatal seizures.[73,94,96] However, children suffer asphyxia either before or during parturition, and only 10% of cases of asphyxia result from postnatal causes.[4,94] When asphyxia is suspected during the labor and delivery process, biochemical confirmation can be attempted.

Intrauterine factors in the hours to days before labor can result in antepartum fetal asphyxia without later documentation of acidosis at birth or immediately before birth. Maternal illnesses such as thrombophilia or preeclampsia, or specific uteroplacental abnormalities such as abruptio placentae or cord compression may contribute to fetal asphyxial stress without providing the opportunity to document in utero acidosis at the end of parturition.[77] Antepartum maternal trauma and chorioamnionitis are additional acquired conditions that cause or contribute to intrauterine asphyxia secondary to uteroplacental insufficiency. Intravascular placental thromboses, infarction of the placenta (fetal or maternal surfaces), or umbilical cord thrombosis noted on placenta/cord examinations postnatally are additional surrogates for remote peripartum or intrapartum fetal asphyxia (see also Chapter 24). Meconium passage into the amniotic fluid may also promote an inflammatory response in the placental membranes, causing vasoconstriction and additional asphyxia. Neuroimaging, preferably with magnetic resonance imaging (MRI), may later define the destructive brain lesions that resulted from in utero asphyxia, even without HIE expressed at birth. Diffusion-weighted MRI provides a shorter time window that may or may not extend before the onset of labor or when the mother entered the hospital, depending on the length of hospitalization before birth and the postnatal age when the MRI was obtained. Therefore asphyxia-induced brain injuries may result from in utero maternal-fetal-placental diseases that later are expressed in part as neonatal seizures, independent of the biochemical marker of acidosis at birth, as well as the evolving HIE syndrome in the days after birth.[4]

Postnatal medical illnesses also cause or contribute to asphyxia-induced brain injury and seizures without HIE, after an uneventful delivery without fetal distress during labor or neonatal depression at birth. Persistent pulmonary hypertension of the newborn (PPHN), cyanotic congenital heart disease, sepsis, and meningitis are principal diagnoses.

A case-control study of term infants with clinical seizures reported a fourfold increase in the risk of unexplained early-onset seizures after intrapartum fever. All known causes of seizures were eliminated, including meningitis or sepsis. These 38 newborns, compared with 152 control subjects, experienced intrapartum fever as an independent risk factor on logistic regression that predicted seizures. The authors speculated on the role of circulating maternal cytokines that triggered “physiologic events” contributing to seizures.[40]

The American College of Obstetricians and Gynecologists[4] has published guidelines that suggest essential or collective criteria to define postasphyxial neonatal encephalopathy (i.e., HIE) after significant clinical depression noted at birth. The report acknowledges that as many as 90% of children have antepartum timing to a brain injury, with the caveat that more recent asphyxial injury may occur either in the intrapartum or peripartum periods up to 48 hours before delivery.

Postasphyxial encephalopathy refers to an evolving clinical syndrome over days after birth depression during which neonatal seizures may occur, usually in children who also exhibit severe early metabolic acidosis, hypoglycemia or hypocalcemia, and multiorgan dysfunction.[70,90] Other epiphenomena around asphyxia may contribute to seizures. Seizures after asphyxia may be associated with trauma, intracranial hemorrhage, or other brain damage based on neurologic diagnoses besides asphyxia.

The physical examination findings of the infant with HIE and seizures include coma, hypotonia, brainstem abnormalities, and loss of fetal reflexes. Postasphyxial seizures usually occur within the first 3 days of life, depending on the length and degree of asphyxial stress during the intrapartum period.[90] An early occurrence of seizures, within several hours after delivery, sometimes suggests antepartum or peripartum occurrence of a fetal brain disorder when associated with specific fetal heart rate patterns. However, seizure onset is not a reliable indicator of timing of fetal brain injury. Earlier seizure onset, within 4 hours of birth, in encephalopathic newborns may predict a particularly adverse outcome independent of etiology for asphyxia.[21]

Asphyxia is conventionally diagnosed based on the association of several metabolic parameters with hypoxia and acidosis. The duration of asphyxia is difficult to assess based on either single or even multiple PO_2 values, and pH levels of less than 7.2 are considered of greater clinical concern for predicting HIE, although the suggested guideline of a pH of less than 7.0 is one criterion by which the clinical entity of HIE might be predicted.[4] A metabolic definition of asphyxia should also include a base deficit of less than 12 mmol/L, although specific researchers suggest a base deficit of less than 16 mmol/L because of its higher predictive power for the emergence of the HIE syndrome, including clinical seizures.[43] One caveat should always be considered before assigning a relative risk to a pH value; elevated PCO_2 values introduce a superimposed respiratory acidosis secondary to hypercarbia. Elevated PCO_2 with respiratory acidosis is comparatively less harmful to brain tissue and is more rapidly corrected by aggressive ventilatory support. Alternatively, metabolic acidosis suggests a more profound alteration of intracellular function that better predicts an evolving brain disorder, which may include seizures as part of HIE.

Low Apgar scores traditionally are associated with infants with suspected neurologic depression after delivery, with possible evolution to HIE and seizures (see also Chapter 26). Low 1- and 5-minute Apgar scores indicate the continued need for resuscitation, but only low scores at 10, 15, and 20 minutes more accurately predict sequelae. Normal Apgar scores, however, do not eliminate the possibility of severe antepartum brain injury, either from asphyxia or other causes. As many as two thirds of neonates who exhibit cerebral palsy at older ages had normal Apgar scores at birth without HIE.[57]

Placental findings may reflect disease states at any time before birth either with or without metabolic acidosis and evolving HIE after birth. Although in utero meconium passage commonly occurs in otherwise healthy newborns, meconium staining of the child’s skin may be correlated with meconium-laden macrophages in placental membranes in a depressed newborn. Meconium staining through the chorionic layer to the amnion suggests a longer-standing asphyxial stress, such as over 4 to 6 hours (see also Chapter 24).

Placental weight below the 10th or above the 90th percentile suggest chronic perfusion abnormalities to the fetus. Microscopic evidence of lymphocytic infiltration, altered villous maturation, chorangiosis, and erythroblastic proliferation of placental villi each support chronic asphyxial stresses to the fetus. In a study of preterm and term neonates (23 to 42 weeks of corrected age) with EEG-confirmed seizures, a significant association between seizures and chronic (with or without acute) placental lesions was noted, increasing to a factor of 12.1 ($P < .003$) by term age. Odds ratios were not significant for infants with seizures and exclusively acute placental lesions, presumably from events closer to labor and delivery.[82]

Specific clinical findings in the depressed neonate with suspected HIE may reflect antepartum disease states.[49] Intrauterine growth restriction, hydrops fetalis, or joint contractures (including arthrogryposis) are findings that suggest remote in utero diseases that may have been associated with antepartum asphyxia and later express as intrapartum fetal distress or neonatal depression. Hypertonicity, often with cortical fisting, in a previously depressed child who rapidly recovers after a resuscitative effort also commonly reflects longer-standing fetal neurologic dysfunction before labor or the mother's admission to the hospital. Sustained hypotonia and unresponsiveness for 3 to 7 days are the expected signs of HIE after asphyxial stress during labor, with or without brain injury.

The encephalopathic newborn with depressed arousal and hypotonia nonetheless may paradoxically reflect an antepartum disease process with neonatal dysfunction or superimposed injury as a result of a problematic intrapartum period. This has been described in neurologically depressed infants with EEG seizures and isoelectric interictal EEG pattern abnormalities who are comatose and flaccid for days, requiring ventilator assistance after difficult deliveries. Children may appear neurologically depressed after asphyxial stress during the intrapartum period (i.e., low Apgar scores and metabolic acidosis). Evidence of antepartum fetal brain injury is supported by preexisting maternal disease, placental lesions, neuroimaging findings, or neuropathologic-postmortem findings. Although intrapartum asphyxial stress worsens brain injury in some children, it is impossible to differentiate neonatal encephalopathy from preexisting antepartum brain injury.

Metabolic Derangements

HYPOGLYCEMIA

Hypoglycemia is usually defined as glucose levels of 35 to 40 mg/dL (see also Chapter 49, Part 1). No clear consensus exists concerning a direct cause-and-effect relationship of hypoglycemia with seizure occurrence. Also, associated disturbances may coexist, such as hypocalcemia, craniocerebral trauma, cerebrovascular lesions, and asphyxia, which may also contribute to lowering the infant's threshold for seizures. Infants born of diabetic or toxemic mothers, particularly those who were small for gestational age, are also at risk for hypoglycemia. Jitteriness, apnea, and altered tone are clinical signs that may appear in children with hypoglycemia but are not representative of a seizure state. Cerebrovascular lesions in posterior brain regions have been reported in children with hypoglycemia. Vulnerability of brain to ischemic insults is enhanced by concomitant hypoglycemia.

HYPOCALCEMIA

Total serum calcium levels below 7.5 to 8 mg/dL generally define hypocalcemia (see also Chapter 49, Part 2). The ionized fraction is a more sensitive indicator of seizure vulnerability. As with hypoglycemia, the exact level of hypocalcemia at which seizures occur is debatable. An ionized fraction of 0.6 mg/dL or less may have a more predictable association with the presence of seizures. Hypocalcemia due to high-phosphate infant formula has been previously cited as a cause of late-onset seizures.[70] However, hypocalcemia now more commonly occurs with a variety of nonspecific problems or asphyxia, and may coexist with hypoglycemia or hypomagnesemia. Rarely, congenital hypoparathyroidism in association with other genetic abnormalities such as DiGeorge syndrome (i.e., velocardiofacial syndrome, or 22q11 deletion with cardiac and brain anomalies) must be considered. These infants may have severe congenital heart disease as well as a hypoparathyroid state with hypocalcemia and hypomagnesemia that precipitates seizures.[45] In infants with hypocalcemia of unknown etiology, the condition may be the result of maternal hypercalcemia. Ascertainment of the mother's calcium status should be considered because maternal hypercalcemia can suppress fetal parathyroid development.

HYPONATREMIA AND HYPERNATREMIA

Hyponatremia is a metabolic disturbance that may result from inappropriate secretion of antidiuretic hormone after severe brain trauma, infection, or asphyxia,[94] but is an uncommon isolated cause of neonatal seizures. (See Chapter 36.)

Hypernatremia also is a rare cause of seizures, and usually is associated with dehydration or iatrogenic disturbance of serum sodium balance by the use of IV fluids with high concentrations of sodium.

Cerebrovascular Lesions

Hemorrhagic or ischemic cerebrovascular lesions are associated with neonatal seizures, on either an arterial or venous basis.[68] (See also Parts 2 and 3 of this chapter.) Intraventricular or periventricular hemorrhage is the most common intracranial hemorrhage of the preterm infant, and has been associated with seizures in as much as 45% of a preterm population with EEG-confirmed seizures. In a cohort of newborns with clinical seizures, intraventricular hemorrhage was the predominant cause of seizures in preterm infants less than 30 weeks' gestational age.[87] Intracranial hemorrhage is usually expected within the first 72 hours of life of the preterm infant. Although intraventricular or periventricular hemorrhage may occur in otherwise asymptomatic infants, the neonate with a catastrophic deterioration of clinical status shows signs of apnea, bulging fontanelle, hypertonia, and seizures.[93] Term infants present less commonly with intraventricular hemorrhage, usually originating from the choroid plexus or thalamus.

Other sites of intracranial hemorrhage which may cause seizures include within the subarachnoid space, but is usually associated with a more favorable outcome. Subdural hematoma, whether spontaneous or with craniocerebral trauma, should always be considered, particularly when focal trauma to the face, scalp, or head has occurred; simultaneous occurrences of cerebral contusion and infarction should also be considered.

Cerebral infarction has been described in neonates with seizures and can result from events during the antepartum, intrapartum, or neonatal periods (see also Parts 2 and 3 of this chapter). Either preterm or term neonates with infarction may also present without seizure expression.[18] Seizures can also occur in otherwise healthy infants, suggesting an antepartum period when cerebral infarction occurred.[50] Aggressive use of neuroimaging during the antepartum period by fetal sonography or MRI, or within the first days after birth, may document remote brain lesions. Destructive lesions such as porencephaly require approximately 5 to 7 days before appearing radiographically. More recent intrapartum or neonatal periods during which injury occurred can be supported by the presence of early cerebral edema using diffusion-weighted MRI.[23] Cerebral infarction may also occur during the postnatal period from asphyxia, polycythemia, dehydration, or coagulopathy.

PPHN with severe and recurrent hypoxia can also be associated with cerebrovascular lesions and seizures (Fig. 40-78; see also Chapter 44). Certain infants with PPHN require extracorporeal membrane oxygenation to treat severe forms of this pulmonary disease which do not respond to traditional ventilatory and nitric oxide therapy. Radiographic documentation of brain lesions needs to be obtained before beginning extracorporeal membrane oxygenation because the anticoagulation required for this procedure may convert “bland” or ischemic infarctions to hemorrhagic forms, with greater risk for cerebral edema and herniation. Although meconium aspiration syndrome has historically been identified with an intrapartum or neonatal presentation of PPHN, in many children with this lung disease the condition reflects antepartum maternal-fetal or placental conditions that predispose the fetus to thickening of the muscular layers of the pulmonary arteries in utero, with resultant sustained increased pulmonary vascular resistance after birth.[6]

Cerebral infarction in the venous distribution of the brain may also lead to neonatal seizures.[68] Lateral or sagittal sinus thromboses after coagulopathy can occur secondary to systemic infection, polycythemia, or dehydration. Venous infarction in the deep white matter of the preterm brain also occurs in association with intraventricular hemorrhage.

Infection

See also Chapter 39.

Central nervous system infections during the antepartum or postnatal periods can be associated with neonatal seizures. Congenital infections, commonly referred to by the acronym *TORCH* (i.e., *t*oxoplasmosis, *r*ubella, *c*ytomegalovirus, and *h*erpes simplex virus), can produce severe encephalopathic damage that results in seizures, as well as more diffuse brain disorders. Other congenital infections include those caused by enteroviruses and parvoviruses. Specific infections such as neonatal herpes encephalitis have been associated with severe EEG pattern abnormalities.[56] Rubella, toxoplasmosis, and cytomegalic inclusion disease also can lead to devastating encephalitis, usually presenting with microcephaly, jaundice, body rash, hepatosplenomegaly, or chorioretinitis. Increasing lethargy and obtundation with or without seizures may suggest the subacute presentation of encephalitis during the postnatal period. Serial spinal fluid analyses document progressively increasing protein or pleocytosis.

Bacterial infections acquired in utero or postnatally from either gram-negative or gram-positive organisms are also associated with neonatal seizures. Some organisms such as *Escherichia coli,* group B streptococci, *Listeria monocytogenes,* and mycoplasmas may produce severe leptomeningeal infiltration, with possible abscess formation and cerebrovascular occlusions. A high percentage of survivors has significant neurologic sequelae.

Central Nervous System Malformations

See also Parts 1 and 7 of this chapter.

Disorders of induction, segmentation, proliferation, migration, myelination, and synaptogenesis of neuronal components can contribute to varying degrees of malformation. Seizures may result in the newborn with malformations who experiences stress around the time of birth,[62] which presumably lowers seizure thresholds. Brain anomalies may occur as a result of either genetic causes from conception or acquired defects during the first half of gestation. Specific dysgenesis syndromes, such as holoprosencephaly and lissencephaly, are often associated with characteristic facial or body anomalies. Cytogenetic studies may document trisomies or deletion defects. Unfortunately, infants may also lack physical clues to the presence of a brain malformation. The clinician’s high index of suspicion is then warranted to evaluate neonates with persistent seizures. Nine percent of 356 infants presenting with neonatal seizures had brain malformations.[87] Neuroimaging, preferably magnetic resonance techniques, documents brain dysgenesis in children who may also express severe EEG disturbances, including seizures (Fig. 40-79). Focal or regional brain malformations are rare causes of early-onset epilepsy in neonates and young infants[2]; functional imaging studies such as positron emission tomography scans[11] may identify localized areas of altered brain metabolism, which can assist in a neurosurgical approach to seizure management, even in young children who fail to respond to antiepileptic drug maintenance.[65]

Inborn Errors of Metabolism

See also Chapter 50.

Inherited biochemical abnormalities are rare causes of neonatal seizures.[46] Intractable seizures associated with elevated lactate and pyruvate levels in blood and spinal fluid may reflect specific inborn errors of metabolism. Dysplastic or destructive brain lesions, as documented on neuroimaging, may be associated with specific biochemical defects, such as glycine encephalopathy or branched-chain aminoacidopathies. Pregnancy, labor, and delivery histories for these infants are commonly uneventful. The emergence of feeding intolerance as well as increasing lethargy, stupor, coma, and seizures is an early indication of an inborn metabolic disturbance during the first few days of life. The newborn with an inherited metabolic disorder may initially present as a neurologically depressed and hypotonic child with asphyxia and seizures. Some children respond to specific dietary therapies, including vitamin supplementation, depending on the enzymatic defect.

Figure 40–79. A, Electroencephalogram segment of 38-week gestation, 1-day-old infant with right hemisphere-predominant generalized electrographic seizures without clinical signs. B, Magnetic resonance image for the patient in A, demonstrating severe cerebral dysgenesis including lissencephaly, holoprosencephaly, and a small, atrophic cerebellum and brainstem. *(From Scher MS: Seizures in the newborn infant,* Clin Perinatol *24:763, 1997, with permission.)*

Specific urea cycle defects, such as ornithine transamylase or carbamoyl phosphate synthetase deficiency, may present with coma and seizures during the first 2 days of life, with marked elevations in plasma ammonia levels. These infants may respond to aggressive treatment with an exchange transfusion, dialysis, and appropriate dietary adjustments.

Vitamin B_6 or pyridoxine deficiency is a rare cause of neonatal seizures.[5] Pyridoxine acts as a cofactor in γ-aminobutyric acid synthesis, and its absence or paucity promotes seizures. The mother occasionally reports paroxysmal fetal movements.[60] The infant who is unresponsive to conventional antiepileptic medications should promptly receive an IV injection of 50 to 500 mg pyridoxine, preferably with concomitant EEG monitoring. Termination of the seizure within minutes to hours as well as resolution of EEG background disturbances suggests a pyridoxine-dependent seizure state. Prophylactic doses of pyridoxine may be needed to achieve and maintain seizure control.

Other rare causes of seizures include disorders of carbohydrate metabolism with coincident hypoglycemia,[46] as well as peroxisomal disorders, such as neonatal adrenoleukodystrophy or Zellweger syndrome. A defect in a glucose transporter protein necessary to move glucose across the blood-brain barrier has also been reported, which results in hypoglycorrhachia and seizures.[17] Such children may achieve seizure control with a ketogenic diet, but nonetheless suffer delayed development.

Molybdenum cofactor deficiency and isolated sulfite oxidase deficiencies are other rare metabolic defects that cause neonatal seizures and associated destructive changes on neuroimaging, which may resemble cerebrovascular disease or asphyxial insults.

Drug Withdrawal and Intoxication

See also Chapter 38.

Newborns born to mothers who engaged in prenatal substance use or abuse may have an increased risk for neonatal seizures. Exposure to barbiturates, alcohol, heroin, cocaine, or methadone commonly presents with neurologic findings that include tremors and irritability. Withdrawal symptoms, in addition to seizures, may occur as long as 4 to 6 weeks after birth; EEG studies are useful to corroborate such movements with coincident electrographic seizures. Certain drugs, such as short-acting barbiturates, may be associated with seizures within the first several days of life. Seizures may occur directly after substance withdrawal, or associated with longer-standing uteroplacental insufficiency promoted by chronic substance use and poor prenatal health maintenance by the mother. Careful review of placental-cord specimens may reveal chronic or acute lesions that contribute to antepartum or intrauterine asphyxia.

Inadvertent fetal injection with a local anesthetic agent during delivery may induce intoxication, which is a rare cause of seizures. Patients present during the first 6 to 8 hours of life with apnea, bradycardia, and hypotonia, and are comatose, without brainstem reflexes. If the obstetric history indicates pudendal administration of an anesthetic to the mother, a careful examination of the child's scalp or body for puncture marks is indicated. Determination of plasma levels of the suspected anesthetic agent establishes the diagnosis. Treatment consists of ventilatory support and removing the drug by therapeutic diuresis, acidification of the urine, or exchange transfusion. Antiepileptic medications are rarely indicated.

Progressive Neonatal Epileptic Syndromes

Progressive epileptic syndromes rarely present during the first month of life.[54] These children usually exhibit myoclonic or migratory seizures that are poorly controlled by antiepileptic medications, with brain malformations often demonstrable on brain imaging.[19] These neonatal epileptic syndromes are termed *early myoclonic encephalopathy* or early infantile epileptic encephalopathy (Ohtahara syndrome), and the EEG commonly documents burst suppression or markedly disorganized background rhythms. Rarely, neonates with idiopathic localization-related or partial seizures without neuroimaging abnormalities present with intractable epilepsy.

Neurocutaneous syndromes, such as incontinentia pigmenti and tuberous sclerosis, may also present during the neonatal period with symptomatic epilepsy as one clinical manifestation of these genetic disorders (see also Chapter 52). Incontinentia pigmenti is accompanied by a vesicular crusting rash that initially mimics a herpetic infection. Seizures may or may not be present. The skin lesions evolve into lightly pigmented, raised sebaceous lesions in older infants and children. Tuberous sclerosis also rarely presents with skin lesions in the newborn period. Hypopigmented lesions, initially noted under ultraviolet light, usually appear later during infancy. Two common fetal presentations of tuberous sclerosis are a cardiac tumor, usually a rhabdomyoma, or rarely a connatal brain tumor, both noted on fetal sonography. Neonatal seizures also may be the presenting feature,[51] with documentation of intracranial lesions on postnatal neuroimaging.

Benign Familial Neonatal Seizures

The autosomal dominant form of neonatal seizures is a rare genetic epilepsy that should be considered in the context of a positive family history. Infectious, metabolic, toxic, and structural causes need to be excluded before considering this entity. The genetic defect was first described on chromosome 20q,[31] specifically at the D20S19 and D20S20 loci, as well as a locus EBN2 on chromosome 8q24. By positional cloning, a potassium channel gene *(KCNQ2)* located on 20q13.3 was first isolated and found to be expressed in brain. A second potassium channel gene *(KCNQ3)* has also been described and may account for the varied phenotypic expression of seizures and outcomes.[37] Mutations in ion channels have also been implicated in Jervell and Lange-Nielsen syndromes, whose symptoms include congenital deafness and cardiac arrhythmias.[31] Infant outcomes range from excellent to guarded, depending on the persistence of seizures beyond the neonatal period. Response to antiepileptic medication is usually good, although some authors describe variable success. Further studies are needed to clarify the relationship between phenotypic and genotypic expressions of this disorder.

DIAGNOSTIC ALGORITHM

Once seizures are confirmed by EEG, the neonatologist and neurologist must place these events into the context of clinical, historical, and laboratory findings to determine the pathogenesis and timing of an encephalopathic process in the symptomatic neonate. Seizures in neonates after asphyxia support either acute intrapartum events or antepartum disease processes. The child with seizures may also express clinical and laboratory signs of evolving cerebral edema. The presence of a bulging fontanelle with neuroimaging evidence of increased intracranial pressure and cerebral edema (i.e., obliterated ventricular outline and abnormalities on diffusion-weighted MRI) strongly suggest a more recent asphyxial disease process, in or around the intrapartum period.

Hyponatremia and increased urine osmolality suggest the syndrome of inappropriate secretion of antidiuretic hormone accompanying acute or subacute cerebral edema.

Alternatively, failure to document evolving cerebral edema during the first 3 days after asphyxia, or documentation of encephalomalacia or cystic brain lesions on neuroimaging shortly after birth (i.e., even in the encephalopathic newborn), suggests a more chronic disease process and remote antepartum brain injury. Liquefaction necrosis requires 2 weeks or longer after the presumed in utero asphyxial event to produce a cystic cavity, which is then visible on neuroimaging.

Isolated seizures in an otherwise asymptomatic neonate can suggest a disease process occurring during either the postnatal or antepartum periods. Neonates present with seizures as a result of postnatal illnesses from intracranial infection, cardiovascular lesions, drug toxicity, or inherited metabolic diseases. Children with antepartum injury may express isolated seizures after in utero cerebrovascular injury on the basis of thrombolytic or embolic disease of the mother, placenta, or fetus. Fetal injury also may occur after ischemia-hypoperfusion events from circulatory disturbances, such as maternal shock, chorioamnionitis, or placental-fetal vasculopathy.[52]

Only a percentage of neonates with in utero cerebrovascular disease present with neonatal seizures. Why others remain asymptomatic until later childhood is unknown. Neonatal expression of seizures may reflect recent physiologic stress during parturition, which lowers seizure threshold in susceptible brain regions that have been previously damaged.

After a careful review of the medical histories of the mother, fetus, and newborn, determination of serum glucose, electrolytes, ammonia, lactate, pyruvate, magnesium, calcium, and phosphorus levels may diagnose correctable metabolic conditions in newborns with seizures who will not require antiepileptic medications. Spinal fluid analyses include cell count, protein, glucose, lactate, pyruvate, amino acids, and culture studies to consider central nervous system infection, intracranial hemorrhage, and metabolic disease. Metabolic acidosis on serial arterial blood gas determinations may alternatively suggest an inherited metabolic disease, particularly if intrapartum asphyxia was not judged to be severe. Absence of multiorgan dysfunction may alert the clinician to other etiologies for seizures besides intrapartum asphyxia. Signs of chronic in utero stress such as growth restriction, early hypertonicity after neonatal depression, joint contractures, or elevated nucleated red blood cell values all suggest longer-standing antepartum stress to the fetus. Identification of genetic or syndromic conditions can contribute to the expression of neonatal encephalopathies independent of asphyxial injury.[22] Careful review of placental and cord specimens can also be extremely useful. Neuroimaging, preferably using MRI, can help locate, grade the severity of, and possibly time an insult.[38] Ancillary studies may include long-chain fatty acids and chromosomal/DNA analyses, as deemed necessary by family and clinical histories. Finally, serum and urine organic acid and amino acid determinations may be needed to delineate a specific biochemical disorder for the child with a persistent metabolic acidosis. Lysosomal enzyme studies are also occasionally considered to diagnose specific enzymatic deficiencies in children with neonatal seizures (see also Chapter 50).

TREATMENT

Rapid infusion of glucose or other supplemental electrolytes should be initiated before antiepileptic medications are considered. Severe hypoglycemia can be typically corrected by IV administration of 2 mL/kg of a 10% dextrose solution, followed by an infusion of approximately 8 to 10 mg/kg per minute and increased as needed. Persistent hypoglycemia may require more hypertonic glucose solutions. Rarely, other pharmacologic measures (e.g., diazoxide) may be needed to establish a glucose level within the normal range (see also Chapter 49, Part 1).

Hypocalcemia-induced seizures should be treated with an IV infusion of 200 mg/kg of calcium gluconate. This dosage may need to be repeated every 5 to 6 hours over the first 24 hours. Serum magnesium concentrations should also be measured because hypomagnesemia may accompany hypocalcemia; 0.2 mg/kg of magnesium sulfate should be given by IM injection. (See Chapter 49, Part 2.) Disorders of serum sodium are rare causes of neonatal seizures.

Pyridoxine dependency requires the injection of 50 to 500 mg of pyridoxine during a seizure with coincident EEG monitoring. A beneficial pyridoxine effect occurs either immediately or over the first several hours. A daily dose of 50 to 100 mg of pyridoxine should then be administered.

If the decision to treat neonates with antiepileptic medications is reached, important questions must be addressed with respect to who should be treated, when to begin treatment, which drug to use, and for how long neonates should be treated. Some authors suggest that only neonates with clinical seizures should receive medications; brief electrographic seizures need not be treated. Others suggest more aggressive treatment of EEG seizures because uncontrolled seizures potentially have an adverse effect on immature brain development.[94]

Phenobarbital and phenytoin remain the most widely used antiepileptic medications. The half-life of phenobarbital ranges from 45 to 173 hours in the neonate; the initial loading dose is recommended at 20 mg/kg, with a maintenance dose of 3 to 4 mg/kg per day. Therapeutic levels are usually suggested to range from 10 to 40 μg/mL, although there is no consensus with respect to drug maintenance.

The preferred loading dose of phenytoin is 15 to 20 mg/kg. Serum levels of phenytoin are difficult to maintain because this drug is rapidly redistributed to body tissues. Blood levels cannot be well maintained using an oral preparation.

Benzodiazepines may also be used to control neonatal seizures. The drug most widely used is diazepam. One study suggests a half-life of 54 hours in preterm infants to 18 hours in term infants. IV administration is recommended because it is slowly absorbed after an IM injection. Diazepam is highly protein bound and displacement of bilirubin from albumin is possible. Recommended IV doses for acute management should begin at 0.5 mg/kg. Deposition into muscle precludes its use as a maintenance antiepileptic medication because profound hypotonia and respiratory depression may result, particularly if barbiturates have also been administered.

Efficacy of Treatment

Studies report varying efficacy with phenobarbital or phenytoin. However, most studies apply only a clinical endpoint to seizure cessation. Coincident EEG studies are now suggested to verify the resolution of electrographic seizures because 30% of neonates may have persistent electrographic seizures after suppression of clinical seizure behaviors even after drug administration.[80] With doses of phenobarbital as high as 40 mg/kg, the rate of seizure control may be up to 85%, and the earlier administration of high-dose phenobarbital in a group of asphyxiated infants was associated with a 27% reduction in clinical seizures together with better outcome than in a group who did not receive high dosages.[25] With EEG as an endpoint to judge cessation of seizures, neither phenobarbital nor phenytoin was effective in controlling seizure activity.[61]

Assay of free or drug-bound fractions of antiepileptic drugs has been suggested to better assess both the efficacy and potential toxicity of antiepileptic drugs in pediatric populations. Drug binding in neonates with seizures has only recently been reported, and can be altered in a sick neonate with organ dysfunction. Toxic side effects may result from elevated free fractions of a drug, which adversely affect cardiovascular and respiratory function. To guard against untoward effects, evaluation of treatment and efficacy must take into account both total and free antiepileptic drug fractions, in the context of the newborn's systemic illness.

New anticonvulsant alternatives to treat seizures are being suggested such as with *N*-methyl-D-aspartate antagonists, and topiramate,[29,42] developed from experimental models of hypoxia-induced seizure activity in immature brain. Such models provide data regarding pharmacologic and physiologic characteristics of neuronal responses after an asphyxial stress that causes excessive release of excitotoxic neurotransmitters,[30] such as glutamate. Specific cell membrane receptors termed *metabotropic glutamate receptors* are sensitive to extracellular glutamate release and may play a role in epileptogenesis and seizure-induced brain damage. Subclasses of metabotropic glutamate receptors will prompt the investigation of novel drugs that block these membrane receptors as the mode of treatment for neonatal seizures.[39]

Other novel treatment alternatives include antiepileptic approaches with older medications such as the diuretic bumetanide. Bumetanide acts by inhibiting the excitatory action of the NKCC1, the chloride cotransporter active within the immature neuron. It has been shown that this tranporter facilitates seizures in the developing brain using an animal model.[19] Bumetanide may also enhance the action of traditional antiepileptic medications such as phenobarbitol.[20]

Innovative treatment strategies will need to consider both the mechanisms underlying seizure expression[44] as well as timing of when the brain injury occurred that subsequently caused the seizures, whether prior to or during parturition.[83]

Discontinuation of Drug Use

The clinician's decision to maintain or discontinue antiepileptic drug use depends on variable factors. Discontinuation of drugs before discharge from the neonatal unit is usually recommended so that clinical assessments of arousal, tone, and behavior will not be hampered by medication effect. However, newborns with congenital or destructive brain lesions on neuroimaging, or those with persistently abnormal results on neurologic examinations at the time of discharge, may suggest to the clinician that a slower tapering of medication is required over several weeks or months. Neonatal seizures rarely reoccur during the first 2 years of life, and prophylactic antiepileptic drug administration need not be maintained past 3 months of age, even in the child at risk. This is supported by a study suggesting a low risk of seizure reoccurrence after early withdrawal of antiepileptic drug therapy in the neonatal period.[26] Also, older infants who present with specific epileptic syndromes, such as infantile spasms, do not respond to the conventional antiepileptic drugs that were initially begun during the neonatal period. This "honeymoon period" without seizures commonly persists for many years in most children, before isolated or recurrent seizures appear.

The potential damage to the developing central nervous system by antiepileptic drugs also emphasizes the need to consider early discontinuation of these agents in the newborn period. Adverse effects on the morphology and metabolism of neuronal cells have been extensively reported from collective research performed over the last several decades.[53]

CONSEQUENCES OF NEONATAL SEIZURES

Embedded in the controversy surrounding the diagnosis of neonatal seizures is the association with altered brain development and poor neurologic outcome. The clinician must first appreciate the diverse neuropathologic processes, independent of the seizure process, associated with specific etiologies responsible for neonatal seizures and neurologic sequelae.[32] Our understanding of the underlying mechanisms responsible for brain damage in neonates with seizures is limited to a few definable factors such as central nervous system infections and severe asphyxia.

Direct effects of the seizure state also may have adverse effects on developing brain.[27] Seizures can disrupt a cascade of biochemical and molecular pathways normally responsible for the plasticity or activity-dependent development of the maturing nervous system. Seizures may disrupt the processes of cell division, migration, sequential expression of receptor formation, and stabilization of synapses, contributing to neurologic sequelae.

Experimental models of seizures in immature animals suggest less vulnerability to seizure-induced brain injury than in mature animals.[28] In adult animals, seizures alter growth of hippocampal granule cells and cause axonal and mossy fiber growth, resulting in long-term deficits in learning, memory, and behavior. A single prolonged seizure in an immature animal, on the other hand, results in less cell loss or fiber sprouting, and consequentially fewer deficits in learning, memory, and behavior. Resistance to brain damage from prolonged seizure activity, however, is age specific, as evidenced by increased cell damage after only 2 weeks of age.[71]

Repetitive or prolonged neonatal seizures increase the susceptibility of the developing brain to subsequent seizure-induced brain injury during adolescence or early adulthood from altered neuronal connectivity rather than increased cell death.[27,84] Neonatal animals subjected to status epilepticus have reduced seizure thresholds at later ages and impairments of learning, memory, and activity levels when stressed with seizures as adults. Proposed mechanisms of injury include reduced neurogenesis in the hippocampus, for example, possibly because of ischemia-induced apoptosis as well as necrotic pathways.[48] Other suggested mechanisms of injury include effects of nitric oxide synthetase inhibition on cerebral circulation, which then contributes to ischemic injury. Neonatal seizures therefore may initiate a cascade of diverse changes in brain development that become maladaptive at older ages, and increase the risk of damage after subsequent insults. Destructive mechanisms such as mossy fiber sprouting in the hippocampus or increased neuronal apoptosis may explain mutually exclusive pathways by which the immature brain suffers altered connectivity and reduced cell number, and thus is “primed” for later seizure-induced cell loss at older ages.

Because of a lack of well-designed studies, these experimental findings unfortunately are not supported by clinical investigations of outcome after neonatal seizures.[53] Better definitions of neonatal seizures of epileptic origin are needed, and the critical seizure duration required to injure brain remains controversial. Overlapping effects of underlying central nervous system injury or dysgenesis from specific etiologies versus seizure-induced brain damage make it difficult to differentiate preexisting brain lesions from the direct injurious effects of seizures themselves. The use of microdialysis probes in white and gray matter of piglet brains subjected to hypoxia indicated elevated lactate/pyruvate ratios after hypoxia, but no direct association with seizure activity.[92] These findings support the conclusion that seizures themselves may not lead to injurious metabolic dysfunction.

Aggressive use of antiepileptic medications contributes both to inaccurate estimation of seizure severity in neonates and possible medication-induced brain injury. Intractable seizures usually require the use of multiple antiepileptic medications. Such drugs impede the clinician’s recognition of prolonged seizures because of the uncoupling phenomenon in which the clinical expression may be suppressed while the electrical expression of seizures continues. Clinical definitions of seizure occurrence and duration consequently underestimate seizure severity, which appears to be associated with increased risk for damage. Antiepileptic drug use also has secondary harmful effects on cardiac and respiratory function, with resultant circulatory disturbances that contribute to brain injury.[53] Finally, antiepileptic drug use may have teratogenetic effects on brain development with exposure over long periods.

PROGNOSIS

The mortality rate of infants who present with clinical neonatal seizures has declined over time. Studies of EEG-confirmed seizures documented a 50% mortality rate in preterm and a 40% rate in term infants during the 1980s; during the 1990s, the mortality rate for both groups of infants dropped below 20%. The incidence of adverse neurologic sequelae, however, remains high for approximately two thirds of survivors. Even if major neurodevelopmental sequelae such as motor deficits and mental retardation were avoided in survivors after neonatal seizures, subtle neurodevelopmental vulnerability may manifest in late teenage years as specific learning difficulties or poor social adjustment,[90] underscoring experimental findings of long-term deficits in animal populations.[27]

Prediction of outcome should also clearly consider the etiology for seizures, such as severe asphyxia, significant craniocerebral trauma, and brain infections. More accurate imaging procedures have heightened our awareness of destructive as well as congenital brain lesions with a higher risk for compromised outcome.

Interictal EEG pattern abnormalities are extremely helpful in predicting neurologic outcome in the neonate with seizures. Major background disturbances such as burst suppression (see Fig. 40-77) are highly predictive of poor outcome, particularly when persistently abnormal findings are still present on serial EEG studies into the second week of life. Ictal patterns alone may not be as accurate for predicting outcome, unless they occur in high numbers, long durations, and multifocal distribution.[47] Normal findings on interictal EEG were associated with an 86% chance of normal development at 4 years of age in 139 neonates with seizures[70]; by contrast, neonates with markedly abnormal EEG background disturbances had only a 7% chance for normal outcome. Therefore in term and preterm infants with seizures, the EEG background may be more predictive of outcome than the presence of isolated sharp-wave discharges. Even the finding of severe EEG abnormalities by single-channel spectral EEG recordings after asphyxia carries a higher risk for sequelae.

Neonates with seizures have a risk for epilepsy during childhood.[95] Based on clinical seizure criteria, epilepsy later develops in 20% to 25% of neonates with seizures. Excluding febrile seizures, the prevalence of epilepsy by 6 to 7 years of age is also estimated to be between 15% and 30% based on EEG-confirmed seizures for an inborn hospital population, two thirds of whom were preterm neonates. This is contrasted to a 56% incidence of epilepsy for an exclusively outborn neonatal population of primarily term newborns with seizures.[14] Epilepsy risk therefore reflects selection bias of specific study groups, as well as referral patterns in different hospital settings.

PART 6

Hypotonia and Neuromuscular Disease

Timothy E. Lotze and Geoffrey Miller

Clinicians who care for newborns are often required to consider the possibility that a neuromuscular disorder might be present in a hypotonic infant. When placed in the supine position, the normal full-term infant shows active movement of flexed limbs. The hips are flexed 70 to 90 degrees and abducted approximately 10 to 20 degrees. If passive extension of the legs at the knees is attempted, resistance is met when the popliteal angle is approximately 90 degrees. When the child is pulled to the sitting from the supine position, only slight head lag is present, and on reaching the sitting position, the head should wobble in the midline for a few seconds. Similarly, a predominance of flexor tone is found in the upper limbs. When the infant is held under the axillae, normal tone prevents the infant from slipping through the examiner's hands, and the infant seems to sit in the air. In horizontal suspension, the limbs are flexed, the back is straight, and the head is maintained in the midline for a few seconds. These findings need to be modified for the premature infant who shows decreasing degrees of flexor tone, depending on gestational age.[3,23]

The weak, hypotonic infant has a decrease in the expected resistance of muscle to stretch, and there is a decrease in spontaneous movement. If supine, the infant lies in a froglike position with abduction of the hips and an abnormal extension of the limbs. When pulled to a sitting position, there is head lag with a lack of compensation when the sitting position is reached. In vertical suspension, decreased tone of the shoulder girdle causes the infant to slip through the examiner's hands, and the legs are more extended than flexed. On horizontal suspension, the back hangs over the examiner's hand, and the head and limbs hang loosely. (For further details, see Chapter 27.)

DIAGNOSIS

Almost any condition that affects the central nervous system (CNS; brain or spinal cord) or peripheral nervous system of a newborn can be expressed by a reduction of tone. Furthermore, most acute or multisystem illness in neonates is accompanied by some degree of hypotonia. Therefore the examiner initially must consider whether the infant is acutely ill from sepsis, organ failure, metabolic dysfunction, or other systemic illness. If these illnesses are not present, the next step is to consider whether a primary disorder of the CNS or the peripheral nervous system is the cause. In general, a central cause leads to a reduction in tone out of proportion to the degree of muscle weakness, and the limbs demonstrate antigravity power.[25]

Although this finding is useful, there are exceptions. In some hypotonic neonates there are abnormalities in both the central and peripheral nervous systems. Examples include congenital muscular dystrophy (CMD), congenital myotonic dystrophy, acid maltase deficiency, cervical spinal cord injury, and some mitochondrial or peroxisomal disorders. In addition, some disorders that are primarily central may initially present with profound hypotonia and weakness. Examples are Prader-Willi syndrome and acute disease such as hemorrhage or infarction involving the deep central gray matter of the brain or spinal cord. Conversely, the infant with a mild congenital myopathy demonstrates some antigravity power in the limbs. Finally, hypotonia might be present in the infant without acute systemic or metabolic illness or abnormalities of the nervous system. In these children, there is an unusual degree of ligamentous laxity such as that seen in Ehlers-Danlos syndrome and osteogenesis imperfecta.

The diagnosis of a neonatal muscle disorder requires a methodical approach similar to that used in the older infant or child. A detailed family, obstetric, and delivery history should be taken. Clues to the presence of a neuromuscular disorder include polyhydramnios, a decrease in fetal movement, and malpresentation, although these conditions can be present in any pregnancy with fetal akinesia (paucity of movement). Information should be obtained about whether there was any birth trauma or asphyxia and on the condition of the infant immediately after delivery.

The general examination begins with observation. Does the infant look sick or distressed? The skin should be examined for pallor, trauma, bruising, or petechiae. Any dysmorphic features or congenital defects of the head, neck, or spine should be noted, as should weight, length, and head size and shape. Each system is then examined with a particular emphasis on respiratory rate, pattern, and diaphragmatic movement; cardiovascular status; the presence of organomegaly; the genitalia; the hips; and the presence of contractures. On neurologic examination, initial observations include the degree of alertness and whether the infant fixes or follows. Posture and spontaneous movements are noted. In particular, movement against gravity should be sought, and the examiner should observe whether movement is greater proximally or distally. When formal examination of the cranial nerves is performed, particular attention should be paid to eye movements. These can be observed as spontaneous movements, elicited by a face or a red ball or induced by gentle rotation of the head (oculovestibular reflex). A lack of fixation or following but movement with the oculovestibular reflex suggests a lesion above the brainstem. If the infant is not in severe distress and there is no possibility of cervical spine injury, the degree of hypotonia is assessed by pulling the infant to a sitting position and holding him or her in vertical and horizontal suspension. Passive movement of the joints can assess power and tone in the limbs more gently. Resistance to gentle shaking of an arm or leg (passivité) also provides a subjective assessment of tone.

During handling, cerebral dysfunction should be suspected if there is fisting or an abnormal primitive reflex. The character of the deep tendon reflexes helps distinguish between an upper or lower motor neuron lesion.* If they are abnormally brisk with clonus, then an upper motor neuron lesion is suggested. If absent, a neuropathic lesion or a severe myopathy is more likely. Assessment of sensation should be attempted because a hereditary sensory neuropathy can present during the neonatal period.[7]

Facial diplegia is a particular finding in some neuromuscular disorders and less likely in others. It can also be an early feature of severe acute basal ganglia damage. Note should be made of the infant's ability to suck and swallow, the pooling of secretions, the character of the cry, and the presence of tongue fasciculations. The latter is most often seen in acute infantile spinal muscular atrophy (SMA), but can be seen in any condition in which there is hypoglossal motor neuron damage, examples of which include storage disorders such as acid maltase deficiency, hypoxic-ischemic damage, and infantile neuronal degeneration.

NEONATAL NEUROMUSCULAR DISORDERS

See also Chapter 50.

Neonatal neuromuscular disorders are caused by lesions that affect specific parts of the neuraxis, including the anterior horn cell, peripheral nerve, neuromuscular junction, or muscle (Box 40-11). Rapid and continuing advances are being made in our understanding of the molecular genetic basis of these disorders.

There are a number of CNS conditions in which hypotonia is of sufficient severity that a neuromuscular disorder should be suspected. These are not discussed in detail here, but they include chromosomal disorders such as Prader-Willi syndrome, multiple minor congenital anomaly syndromes, and metabolic multisystem disorders.

BOX 40–11 Neonatal Neuromuscular Disorders

ANTERIOR HORN CELL
Traumatic myelopathy
Hypoxic-ischemic myelopathy
Acute infantile spinal muscular atrophy
Infantile neuronal degeneration
Neurogenic arthrogryposis

CONGENITAL MOTOR AND SENSORY NEUROPATHY
Hypomyelinating neuropathy
Congenital hypomyelinating neuropathy
Charcot-Marie-Tooth disease
Dejerine-Sottas disease
Hereditary sensory and autonomic neuropathy

NEUROMUSCULAR JUNCTION
Acquired transient neonatal myasthenia
Congenital myasthenia
Infantile botulism
Magnesium toxicity
Aminoglycoside toxicity

CONGENITAL MYOPATHY
Nemaline myopathy
Central core disease
Myotubular myopathy
Multi-minicore myopathy

MUSCULAR DYSTROPHY
Congenital muscular dystrophy with merosin deficiency
Congenital muscular dystrophy without merosin deficiency
Walker-Warburg syndrome
Muscle-eye-brain disease
Fukuyama-type congenital muscular dystrophy
Congenital myotonic dystrophy
Duchenne dystrophy (Xp21-linked dystrophinopathy)
Early infantile facioscapulohumeral dystrophy

METABOLIC AND MULTISYSTEM DISEASE
Mitochondrial disorder
Peroxisomal disorder
Neonatal adrenoleukodystrophy
Cerebrohepatorenal syndrome (Zellweger syndrome)
Pompe disease (acid maltase deficiency)
Severe neonatal phosphofructokinase deficiency
Severe neonatal phosphorylase deficiency
Debrancher deficiency
Carnitine deficiency

SPINAL MUSCULAR ATROPHIES

The SMAs are predominantly autosomal recessive disorders characterized by degeneration of the anterior horn cells in the spinal cord and motor nuclei in the lower brainstem. The most frequent and best known is infantile SMA, also called *Werdnig-Hoffmann disease* (SMA type I).[38] Approximately 95% of individuals with SMA are homozygous for a deletion of exon 7 of the survival motor neuron (SMN) gene (*SMN1*) on chromosome 5q13.[59] Although the phenotype varies in severity and age of onset, the acute infantile subtype is well defined and often presents during the neonatal period. This phenotype tends to "run true" in families. Clinically, infants exhibit a severe symmetric flaccid paralysis, which is characteristically greater in the lower limbs than in the upper limbs and greater proximally than distally.

The onset of this weakness is often identified by the mother, who experiences a decrease or loss of fetal movement during late pregnancy. Respiratory muscle function is poor in the infant. However, it is the intercostal muscles that are weak because there is relative sparing of the diaphragm. This gives rise to abdominal breathing and a later characteristic bell-shaped deformity of the chest. Deep tendon reflexes are absent or difficult to elicit. The upper cranial nerves are spared, giving rise to an infant with an alert expression, a furrowed brow, and normal eye movements. The bulbar muscles are weak, which is reflected by a weak cry, poor suck and swallow reflexes, pooling of secretions, aspiration, and tongue fasciculations. Cardiac muscle is not affected, and classic arthrogryposis is usually not a feature although rarely it can be.

---

*An upper motor neuron lesion involves descending motor tracts in the brain and spinal cord, whereas a lower motor neuron lesion involves either the anterior horn cell, peripheral motor nerve, or muscle.

Nerve conduction testing demonstrates normal or slightly decreased motor nerve conduction velocities and normal sensory nerve action potentials. Electromyography shows abnormal spontaneous activity with fibrillations and positive sharp waves as well as an increased mean duration and amplitude of motor unit action potentials, some of which are polyphasic. Serum creatine kinase activity is normal or only slightly elevated. Muscle biopsy reveals large groups of circular atrophic type 1 and 2 muscle fibers (Fig. 40-80). These fibers are interspersed among fascicles of hypertrophied type 1 fibers, which are three or four times normal size and represent fibers reinnervated by sprouting of surviving nerves.[38] This pattern might not be seen during the neonatal period, when there is often only widespread atrophy of type 1 and 2 muscle fibers, making histologic diagnosis difficult. However, a later biopsy should show evidence of reinnervation with large hypertrophied fibers and group atrophy.

The infant who presents during the neonatal period with severe acute infantile SMA characterized by profound hypotonia and weakness rarely survives beyond 1 year of age. It is the severity of weakness at the onset that determines outcome in SMA rather than the age of onset, although in most cases the earlier the onset, the greater the weakness. Artificial ventilation of an infant with severe early-onset SMA leads to an alert but completely paralyzed infant who is totally ventilator dependent.[38]

With the identification of the *SMN* gene in 1995, the diagnosis of SMA has been greatly facilitated, limiting the need for more invasive investigations. Additional understanding of the molecular genetics and protein function may provide insight into potential therapies for this otherwise fatal condition. The SMN coding region on chromosome 5q11.2-13.3 contains a telomeric and centromeric copy of the *SMN* gene, designated *SMN1* and *SMN2*, respectively. These genes are nearly identical in their coding sequence. A single nucleotide polymorphism (840C>T) in SMN2 causes disruption of normal translation.[48] The resultant protein produced by the centromeric copy is often truncated and nonfunctional. SMN2 can produce a small amount of full-length protein, providing partial compensation for mutations in SMN1, but the majority must be produced by SMN1. A direct relationship exists between the number of copies of the SMN2 gene and the age of disease onset, with the SMA type I phenotype correlating with the lowest number of SMN2 gene copies. The exact function of SMN protein remains to be further defined, but it appears to have a critical housekeeping function in the metabolism of motor neuron cell RNA.[5]

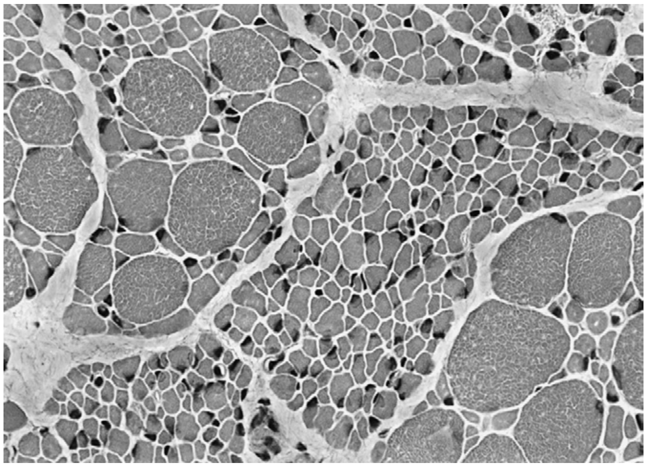

Figure 40–80. Histologic section of muscle showing spinal muscular atrophy. Groups of circular atrophic fibers are interspersed among fascicles of hypertrophied type 1 fibers. Low magnification. *(Courtesy of Hannes Vogel, MD, Baylor College of Medicine, Houston.)*

There are a number of genetically heterogeneous SMA variants, but most of these do not present during the newborn period. Those that might, include SMA with pontocerebellar hypoplasia, X-linked SMA with arthrogryposis due to mutations in the *UBE1* gene, and SMARD1 (distal infantile SMA with diaphragm paralysis) that is due to mutations in the IGHMBP2 gene in most congenital cases.

Arthrogryposis multiplex congenita is a heterogeneous group of disorders characterized by multiple immobilized joints and degeneration of motor neurons. It is most frequently of neurogenic origin and is found in conjunction with other disorders of the CNS, genetic syndromes, or chromosomal aberrations. The neurogenic arthrogryposes are genetically heterogeneous, and both autosomal recessive and X-linked inheritance have been reported.[11,42] A subgroup of neurogenic arthrogryposis is allelic with SMA type I, and deletions of *SMN* gene have been reported.[11] These disorders are of variable severity. Some show no progression, and muscle strength can even improve. In other cases, bulbar and respiratory function is severely affected, and the prognosis is poor. In the X-linked form, there is disease progression and early death.[42]

Traumatic high cervical spinal cord injury (see Chapter 28) is a rare cause of myelopathy that can be misdiagnosed as SMA. In the absence of an asphyxial brain injury, the infant is alert with no cranial nerve signs. The myelopathy is manifested as a flaccid areflexic paralysis, which might be asymmetric. Clues to the diagnosis include evidence of trauma such as bruising or fractures and normal results on cranial nerve examination. After a few days, evidence of the myelopathy becomes more apparent with the appearance of bladder distention, priapism, and an absence of sweating below the level of the spinal lesion. A particularly useful later sign is withdrawal to a noxious stimulus in a limb that shows no spontaneous activity. Sensory testing is difficult but can be assessed by demonstrating facial grimacing to a prick on the face but no response below the neck (see Chapter 28).

In severe hypoxic-ischemic injury there can be an areflexic flaccid paralysis resulting from death of spinal motor neurons.[15] However, there are also signs of an encephalopathy and multiorgan system damage.

HEREDITARY MOTOR AND SENSORY NEUROPATHIES

The hereditary motor and sensory neuropathies are a genetically heterogeneous group of disorders with a spectrum of phenotypes that includes Charcot-Marie-Tooth disease types 1 and 2, hereditary neuropathy with liability to pressure palsies, Dejerine-Sottas syndrome, and congenital hypomyelinating neuropathy. These diseases may demonstrate an autosomal dominant, autosomal recessive, or X-linked mode of inheritance. Charcot-Marie-Tooth disease type 1 and hereditary neuropathy with liability to pressure palsies are demyelinating neuropathies, whereas Charcot-Marie-Tooth disease type 2 is an axonal disorder. Congenital onset is unusual, and these three forms of hereditary motor and sensory neuropathy most often present in the older child or young adult.[61] Congenital hypomyelinating neuropathy and Dejerine-Sottas syndrome are more often described in the infant with a congenital or early infantile onset of demyelinating neuropathy, respectively.[38,60]

Clinical manifestations vary. Affected infants are weak, hypotonic, and areflexic. The weakness is generalized, but a greater distal weakness might be detected. Arthrogryposis may be present in more severe forms. There are usually swallowing and respiratory difficulties. Sometimes facial weakness is present, but extraocular movements are usually normal. Any associated sensory loss is difficult to detect clinically. Prognosis depends on the initial degree of weakness. In some cases there is an improvement in strength.[29]

The disorders are characterized by markedly decreased motor nerve conduction velocities (typically less than 10m/s) and an elevated cerebrospinal fluid protein. Sural nerve biopsy in relatively mild cases shows varying degrees of hypomyelination with atypical onion-bulb formation. More severe cases may show complete lack of myelin.[38] These disorders result from mutations in different genes. Moreover, different mutations in the same gene causes different phenotypes (Charcot-Marie-Tooth disease type 1, Dejerine-Sottas syndrome, congenital hypomyelinating neuropathy), and, at present, the clinical phenotype cannot always be predicted on the basis of the gene mutation. Identified alleles include Schwann cell genes involved in the formation, structure, and maintenance of peripheral myelin *(EGR2, PMP22, MPZ, CX32, 6JB1, PRX)*, neuronal genes involved in axonal transport *(NEFL)*, and genes affecting both Schwann cell and neuronal structure *(MTMR2)*.[58,59] Testing for these mutations is available on a clinical basis.

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHIES

The hereditary sensory and autonomic neuropathies are characterized by selective involvement of peripheral sensory and autonomic neurons (Box 40-12). These disorders are autosomal recessive with the exception of hereditary sensory and autonomic neuropathy type I, which is autosomal dominant. All present with varying degrees of autonomic dysfunction or insensitivity to pain and temperature.[38] In some, there is absence of the normal axonal flare response to intradermal injection of histamine. In the older child there is striking self-mutilation.

BOX 40–12 Hereditary Sensory and Autonomic Neuropathies

- HSAN type I (hereditary sensory radicular neuropathy, autosomal dominant)
- HSAN type II (congenital sensory neuropathy)
- HSAN type III (Riley-Day syndrome, or familial dysautonomia)
- HSAN type IV (congenital insensitivity to pain with anhidrosis)
- HSAN type V (congenital insensitivity to pain with partial anhidrosis)
- Progressive pan-neuropathy and hypotonia
- Congenital autonomic dysfunction with universal pain loss
- Familial amyloid neuropathy (autosomal dominant)

The best known of the hereditary sensory neuropathies is familial dysautonomia (Riley-Day syndrome; hereditary sensory and autonomic neuropathy type III). This disorder has a high carrier rate in individuals of Ashkenazi Jewish descent and has been mapped to chromosome 9q31-q33. Mutations in the gene for IκB kinase-associated protein *(IKBKAP)* account for 99% of affected individuals.[7] The clinical diagnosis of familial dysautonomia is based on five cardinal criteria: (1) absence of overflow tears, (2) absence of lingual fungiform papillae, (3) depressed patellar reflexes, (4) lack of axonal flare reaction after intradermal injection of histamine, and (5) Ashkenazi Jewish extraction. Additional clinical features typically include hypotonia, labile temperature and blood pressure, breath holding, pallor, poor feeding, failure to thrive, vomiting, loose stools, and irritability.

Treatment of these disorders is mainly supportive and survival has improved with modern medical therapies. Patients who reach adulthood continue to demonstrate slow progression of their disease. Cognition may be impaired in some forms of the disease.[6]

Clinical testing is available for familial dysautonomia. Until more molecular genetic information is available, differentiating between the other various hereditary sensory neuropathies will continue to be made by distinct characteristics of the history and examination, sensory nerve conduction and action potential size, and changes on sural nerve biopsy.[6]

NEUROMUSCULAR JUNCTION DISORDERS

Neuromuscular junction disorders are infrequent causes of weakness during the neonatal period. The principal conditions include transient acquired neonatal myasthenia, congenital myasthenia, infantile botulism, and toxic amounts of magnesium or aminoglycosides. These disorders are characterized by abnormal neuromuscular transmission, which is manifested by abnormal muscle fatigability and weakness that is sometimes permanent, particularly in the congenital forms.

Autoimmune myasthenia gravis in children and adults is caused by autoantibodies directed against neuromuscular junction proteins. In 80% of patients, acetylcholine receptor antibodies are detected in the serum. In the remaining patients, other pathologic antibodies, including those directed against muscle-specific kinase, interfere with the normal function of the acetylcholine receptor, resulting in disease.[66]

In acquired neonatal myasthenia gravis, the disease is more often active in the mother. However, she may have less obvious disease, be in remission, or not show clinical manifestations until after the pregnancy.[66] Transfer of immunoglobulin G antibodies occurs readily across the placenta. However, typical features develop in only 20% of infants born to mothers with myasthenia.[36,68] The proportion of maternal immunoglobulin G antibodies directed against the fetal type versus the adult type of acetylcholine receptor appears to have a strong influence on neonatal manifestations. Although there is no correlation between maternal antibody titers or disease severity and the development of neonatal myasthenia, there is an inverse relationship between maternal disease duration and the incidence of neonatal myasthenia. Maternal thymectomy may be protective against neonatal disease.[22]

The disorder usually presents within a few hours of birth, and onset after the third day has not been reported.[52,53] The most common presentation is generalized weakness and hypotonia.[49] Bulbar weakness is usually present, with feeding difficulties from poor sucking and swallowing, and a weak cry. Facial diplegia can be prominent, but ptosis and ophthalmoplegia are seen less frequently. Pooling of secretions and respiratory difficulties occasionally necessitate artificial ventilation. Deep tendon reflexes are normal. Assuming a correct diagnosis and management, most infants recover within a few weeks.[53] Some infants are severely affected with a history of polyhydramnios and the presence of arthrogryposis multiplex at birth.[21] Treatment is more difficult, and recovery is slower in these infants.

The diagnosis of transient neonatal myasthenia should always be suspected in the infant of a mother with active generalized acetylcholine receptor antibody-positive myasthenia gravis. When signs appear, a cholinesterase inhibitor is administered and the response gauged. To be sure of the diagnosis, an unequivocal and objective response should be chosen, such as an improvement in ventilation and oxygenation or sucking ability. IM or SC neostigmine methylsulfate in a dose of 0.15 mg/kg is the preferred diagnostic anticholinesterase agent. The drug takes effect within 15 minutes of injection and lasts 1 to 3 hours. Muscarinic side effects (diarrhea, increased tracheal secretions) might require the use of atropine in appropriate doses. Although edrophonium chloride has a more rapid onset and less intense muscarinic side effects, there is a risk of respiratory arrest.[53] When necessary, the diagnosis can be confirmed with repetitive nerve stimulation,[34] which should be performed before and after the administration of a cholinesterase inhibitor. A diagnostically positive response occurs when the amplitude of the fifth evoked compound muscle action potential is reduced by 10% or more of the amplitude of the first response, and this decrement is corrected by a cholinesterase inhibitor.[53]

The management of transient neonatal myasthenia gravis must be early and vigorous because these infants can deteriorate rapidly. Small, frequent tube feedings should be given and early ventilatory support considered. Neostigmine methylsulfate is given in a dose of 0.05 to 0.1mg/kg, IM or SC, 30 minutes before feeding. The oral dose of neostigmine is approximately 10 times the intramuscular dose and is given approximately 45 minutes before feeding. Excessive doses can cause diarrhea, increased secretions, muscle fasciculations, and cholinergic weakness. Disappearance of disease activity is monitored clinically by assessing responses to gradual decreases in the anticholinesterase dose. In addition, repetitive nerve stimulation tests can be performed as well as measurement of acetylcholine receptor antibodies. Tube feeding and artificial ventilation are usually not required for longer than 1 to 2 weeks, and the average duration of treatment is 4 weeks, with recovery in 90% of infants in less than 2 months.[53]

The congenital myasthenic syndromes are infrequent causes of neuromuscular junction failure during the neonatal period but have become increasingly recognized. They are a group of genetic disorders that are acetylcholine receptor antibody negative and are caused by either presynaptic or postsynaptic inherited defects of the neuromuscular junction. Their precise characterization requires sophisticated laboratory techniques, which are not widely available.[27] Those manifested during the neonatal period are shown in Box 40-13. Unlike acquired transient neonatal myasthenia gravis, ptosis is usually present in addition to varying degrees of ophthalmoplegia, bulbar palsy, and respiratory weakness. Fluctuating, generalized hypotonia and weakness are seen, and episodes of life-threatening apnea can occur. Exacerbations can be induced by activity, febrile illness, or other stress. The disorder often improves with age, but spontaneous exacerbations occur with a risk of sudden infant death. Arthrogryposis has been reported in one form of the disease.[27] A diagnostic response to cholinesterase inhibitors is variable but useful when positive. Some forms of the disorder, such as congenital endplate cholinesterase deficiency, are refractory to or worsened by cholinesterase inhibitors. The diagnosis is supported by a decremental response to repetitive nerve stimulation at low frequency (2 Hz). However, the low-frequency decremental response can be absent in infants with a defect in acetylcholine resynthesis or packaging, but can be induced by prolonged 10-Hz stimulation.

A number of toxic agents disturb neuromuscular transmission in the newborn. Hypermagnesemia, usually secondary to IV administration of magnesium sulfate to the mother, causes a presynaptic failure of acetylcholine release by blocking calcium release.[56] The infant shows profound generalized weakness, areflexia, and respiratory dysfunction. In addition, the CNS and smooth muscle are affected, giving rise to stupor and an ileus. Exposure to excessive amounts of aminoglycosides, particularly in conjunction with neuromuscular blockers, can be followed by prolonged weakness from a presynaptic block. Bladder, bowel, and pupillary function are affected.[68,71] Both hypermagnesemia and the neurotoxic effects of aminoglycosides are worsened by hypocalcemia.

Infantile botulism affects infants between 2 weeks and 6 months of age (see Chapter 39).[17,30,68] Unlike botulism in children and adults, which is caused by ingesting the

Rapsyn deficiency
Plectin deficiency

exotoxin of *Clostridium* botulinum, infantile botulism occurs when the intestine is colonized by the clostridia bacteria, where they produce their toxin. This toxin causes a presynaptic cholinergic blockage that affects autonomic as well as skeletal and smooth muscle function. The disorder has a clinical spectrum. Presentation varies from mild constipation and hypotonia to unexpected death. The classic form of the disorder presents with constipation and poor feeding followed by progressive hypotonic weakness and loss of deep tendon reflexes. There is usually marked cranial nerve dysfunction, which includes pupillary paralysis and ptosis. The weakness often progresses in a descending fashion. The illness usually lasts 1 to 2 months but relapses in a small number of patients.[30] Diagnosis is made by demonstrating an incremental response to repetitive nerve stimulation at high rates (20 to 50 Hz) and by the appearance of short-duration, low-amplitude motor unit potentials on electromyography.[39] Confirmation of the diagnosis is made on isolation of the organism from the stool. Prompt treatment with human-derived botulism immunoglobulin may significantly reduce the length of time needed for clinical recovery.[55] Management is otherwise supportive.

CONGENITAL MUSCULAR DYSTROPHY

The CMDs are a variable group of autosomal recessive disorders that share the common presentation of weakness and hypotonia at birth in conjunction with a dystrophic muscle biopsy. The muscle biopsy typically shows endomysial and perimysial connective tissue proliferation, replacement of muscle by fat, and variations in muscle fiber size (Fig. 40-81). There is little evidence of necrosis or regeneration. Immunocytochemical studies help distinguish between different types.[14,51] Clinically, muscular weakness is generalized and usually involves the face. Bulbar and respiratory muscle involvement is variable but can be severe. The creatine kinase level is elevated in some types but is normal or only moderately elevated in others.[38] Arthrogryposis is a common feature.

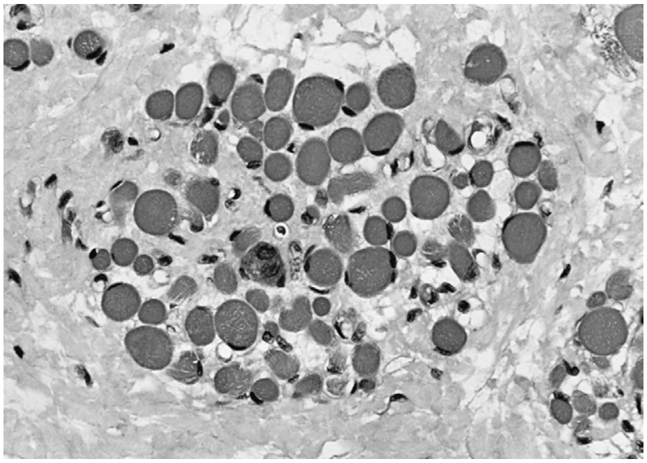

Figure 40–81. Histologic section of muscle showing congenital muscular dystrophy. The biopsy shows connective tissue proliferation, replacement of muscle by fat, and variations in fiber size. Low magnification. *(Courtesy of Hannes Vogel, MD, Baylor College of Medicine, Houston.)*

The CMDs have historically been divided into the nonsyndromic ("classic") forms, typified by normal cognition, and the syndromic forms, associated with brain malformations and mental retardation (Box 40-14). This distinction between the classic and syndromic forms has been blurred by advances in molecular genetics showing similarities between the groups and reports of classic CMD presenting with posterior pachygyria in association with cognitive defects.[41]

The classic forms are subdivided into merosin-positive and merosin-negative subtypes. The merosin-negative form accounts for nearly 50% of all CMDs. Merosin is the heavy α2 chain of the heterotrimeric protein laminin 2 (Fig. 40-82). By linking the extracellular matrix with transmuscle-membrane dystrophin-associated glycoproteins, the protein plays a critical role in myogenesis and myotubule membrane stability. It is also expressed in Schwann cells, trophoblasts, skin, and cerebral blood vessels. Mutations in the α2-laminin gene *(LAMA2)* on chromosome 6q are responsible for the disease. Mutation screening is impractical for clinical use because no single mutation predominates in this large gene. Diagnosis is best achieved with muscle biopsy showing complete absence of merosin with immunocytochemical staining.[14]

The CMDs can be classified according to the protein defect, and in many cases this can be identified by immunocytochemistry or DNA analysis.[51] Abnormalities of extracellular matrix protein defects include laminin α2–deficient CMD (MDC1A) and collagen 6A deficiencies as in Ullrich CMD (UCMD 1, 2, and 3); integrin α7 deficiency (ITGA7); abnormalities of glycosyltransferases, which lead to abnormal O-glycosylation of α-dystroglycan, and include o-mannosyltransferase 1 (POMT1), o-mannosyltransferase 2 (POMT2), o-linked mannose β1,2-N-acetyl glucosaminyl transferase (POMGnT1), fukutin, fukutin-related protein (FKRP), and Lacetylglucosaminyltransferase like protein (LARGE); and endoplasmic reticulum proteins such as selenoprotein N, which causes rigid spine syndrome (RSMD1).

The clinical presentation of merosin deficiency typifies the classic form of the CMDs. There is marked neonatal hypotonia with generalized weakness and atrophy. Although facial weakness may be present, the eye muscles are spared. Contractures occur early and affect multiple joints. Involvement of chest wall muscles results in respiratory difficulties. Cognition is usually not affected. Other clinical features of merosin

deficiency include a peripheral neuropathy, reflecting absence of merosin expression in Schwann cells. In addition, neuroimaging shows white matter changes, most appreciable after 6 months of age. The abnormality is best characterized by diffuse increased signal intensity on T2-weighted magnetic resonance imaging sequences. These findings are thought to correlate with lack of merosin in the cerebral vessel walls.[65] A small minority of patients show structural dysgenesis with occipital pachygyria or agyria. Epilepsy is encountered in one third of patients.[40]

Although similar in presentation, the other forms of classic CMD can be differentiated based on distinct clinical features and underlying molecular genetics. Ullrich CMD is associated with mutations in the protein subunits of type VI collagen and presents with rigidity of the spine and distal joint hyperextensibility.[19,35] Distinct from Ullrich CMD, CMD with rigid spine is associated with early rigidity of the spine and restrictive lung disease. A considerable number of these patients have been found to have mutations of the selenoprotein N gene on chromosome 1p36-p35.[47] Selenoprotein N mutations have also been described in patients with multiminicore disease, a type of congenital myopathy. The function of the protein is unknown. Mutations of the gene for fukutin-related protein on chromosome 19q13 may result in either a severe CMD (CMD type 1C, or MDC1C) or childhood-onset limb-girdle muscular dystrophy.[40] Fukutin-related protein is a putative glycosyltransferase, and similar to the syndromic CMDs (discussed later), this form is associated with defective glycosylation of α-dystroglycan protein in the muscle membrane (see Fig. 40-82). A secondary merosin deficiency is also present on histochemical staining.[14] CMD with a partial merosin deficiency has been defined in a number of patients by biochemical studies. The partial deficiency is thought to be secondary to an underlying α-dystroglycan abnormality with abnormal binding of associated proteins. Linkage to chromosome 1q42 has been made in some of these cases.[9]

The syndromic forms of CMD are associated with brain malformations and ocular findings. The three main types are Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama CMD. All three forms result from mutations in genes encoding distinct glycosyltransferases and related proteins involved in post-translational modification of α-dystroglycan, a pathogenetic mechanism shared by the more classic phenotype MDC1C, as previously discussed.[40] Muscle membrane integrity is compromised by the defective α-dystroglycan, which is unable to bind effectively with either extracellular laminin or transmembranous β-dystroglycan (see Fig. 40-82). Muscle biopsy immunocytochemical techniques demonstrate the abnormal α-dystroglycan expression.[14,51] In the brain, abnormal α-dystroglycan on glial scaffolds, neurons, and their processes is associated with neuronal migrational defects that include disarray of cerebral cortical layering, fusion of the cerebral hemispheres and cerebellar folia, and aberrant migration of granule cells. Disruption of the glial limitans results in cobblestone lissencephaly.[50,51]

Walker-Warburg syndrome is the most severe of the syndromic CMDs. Few infants survive for more than a few months, although prolonged survival is possible with modern medical techniques. Along with muscular dystrophy, typical features of the syndrome include cobblestone lissencephaly with agenesis of the corpus callosum, cerebellar hypoplasia, hydrocephalus, and encephalocele.[50] In contrast with other forms of lissencephaly, there is dysmyelination with the white matter appearing dark on computed tomography scan and abnormally bright on T2-weighted magnetic resonance images. Ocular findings can include cataracts, microphthalmia, buphthalmos, persistent hyperplastic primary vitreous, and Peter anomaly.[16] Some patients with Walker-Warburg syndrome have been found to have mutations in the protein *O*-mannosyltransferase *(POMT1)* gene. The gene encodes an enzyme potentially involved in the biosynthesis of specific glycans associated with dystroglycan. The lack of *POMT1* mutations in many patients with Walker-Warburg syndrome suggests genetic heterogeneity.[50]

Muscle-eye-brain disease has many features in common with Walker-Warburg syndrome but is less severe.[16] Brain malformations can include cobblestone lissencephaly, absent septum pellucidum, dysgenesis of the corpus callosum, hydrocephalus, and white matter changes similar to Walker-Warburg syndrome. Eye findings include myopia, choroidal hypoplasia, optic nerve pallor, glaucoma, iris hypoplasia, cataracts, and colobomas. Newborns present with hypotonia, weakness, feeding difficulties, poor vision, and apathy. Distal contractures can be present. All infants ultimately exhibit mental retardation and seizures. In contrast to Walker-Warburg syndrome, most infants have a prolonged survival. However, independent ambulation is unusual. The development of high-amplitude visual evoked potentials by 2 years is a particular feature, and the electroencephalogram is always abnormal by 1 year of age.[26] A significant number of patients with muscle-eye-brain disease have mutations in the gene coding for the glycosyltransferase POMGnT1.[72]

Fukuyama CMD is almost entirely confined to Japan. Overall, the brain and ocular manifestations are less severe than in Walker-Warburg syndrome and muscle-eye-brain disease. A large proportion of patients have mutations of the fukutin gene on chromosome 9q31. The protein function is unknown. Muscle biopsy staining reveals absence of fukutin as well as abnormal glycosylation of α-dystroglycan.[14] In the brain, the cerebral cortex has a cobblestone appearance with pachygyria and polymicrogyria, but there are also areas with normal gyral patterns.[64] As with Walker-Warburg syndrome, partial obstruction of the subarachnoid space and hemispheric fusion are seen. Other abnormalities, which differentiate the condition from Walker-Warburg syndrome, include white matter changes, which improve with age, and only mild ventriculomegaly and cerebellar polymicrogyria. Cerebellar and pyramidal tract hypoplasia are probably not features. Eye anomalies are minor and typical of Fukuyama-type CMD. Affected infants present with generalized weakness, hypotonia, and varying degrees of muscle contractures. Facial and bulbar involvement is usually present. Seizures are frequent, and mental retardation is moderate or severe. Survival into adolescence is typical.

CONGENITAL MYOTONIC DYSTROPHY

Myotonic dystrophy is an autosomal dominant multisystem disorder of variable expression that is characterized by muscular dystrophy and myotonia in adults. In addition to involvement of muscle, many other systems are affected, including the gastrointestinal, endocrine, and skeletal systems, as well as the heart, brain, and eyes.[32,44] Two loci for the disease have been found and are characterized as DM1 and DM2. The genetic basis for DM1 is an expansion of CTG repeats in the myotonic dystrophy protein kinase (DMPK) gene on chromosome 19q13.3.[12] An amplification of greater than 45 repeats is usually associated with disease expression. DM2 is associated with a CCTG tetranucleotide expansion in the zinc finger 9 *(ZNF9)* gene on chromosome 3q21.[43] DM1 has a more severe clinical phenotype, with a progressively earlier onset in successive generations (genetic anticipation). Congenital myotonic dystrophy is the earliest presenting form of DM1, and it is an important cause of neonatal neuromuscular dysfunction, with an incidence of at least 1 in 3500 live births. These infants usually have greater than 1000 CTG repeats at the DMPK locus. Nuclear accumulation of the abnormal messenger RNA generated by this large repeat size is thought to cause a delay in the differentiation and maturation of skeletal muscle.[1] With rare exceptions, the disease is inherited from the mother.[73] This is related to oligospermia in male patients as well as a greater propensity for larger repeat expansions (more than 1000) during oogenesis than during spermatogenesis.[37,44] The earlier the onset of the disease in the mother and the more severe the clinical expression, the greater the risk for congenital myotonic dystrophy.[33,57] However, the disease can still be seen in offspring of only mildly affected mothers. The phenotypic variation in tissue expression is probably the result of somatic instability of the CTG repeat.[70]

At birth, affected infants frequently require resuscitation and are subject to the mortality and morbidity associated with hypoxic-ischemic encephalopathy (see Part 4 of this chapter). A history of polyhydramnios (from failure of fetal swallowing) and decreased fetal movements is frequent, and premature birth can complicate the diagnosis. Furthermore, delivery can be complicated by prolonged labor and postpartum hemorrhage because of poor uterine contractions.[32,57] Generalized weakness and hypotonia in the infant are profound, with facial diplegia and a characteristically tent-shaped triangular upper lip. Deep tendon reflexes are absent or difficult to elicit, and congenital talipes (clubfoot) is often present. Occasionally, joint contractures are more widespread.[32] There is often respiratory distress, and poor suck and swallow reflexes present the danger of aspiration. Eye movements are full, although the infant might not readily fix and follow. Poor respiratory function is due not only to muscle weakness but also to pulmonary immaturity and poor central respiratory control.[32] An elevated diaphragm on the right can be seen on radiographic examination and is probably due to the presence of the liver on that side and weak diaphragmatic muscles. Hydrops fetalis can occur in infants with cardiac failure. Laboratory investigations in general are not helpful, and the creatine kinase level is normal. The pathologic appearance of muscle differs from that in adults. The fibers are small and round with central nucleation and display poor fiber type differentiation or relatively small type 1 fibers, giving an immature appearance.[1] The typical adult features appear later. Electromyography is often noncontributory because of poor movement, although myopathic potentials can be demonstrated. Clinical and electrical myotonia are not present but appear later, during early childhood. Neuroimaging reveals ventriculomegaly, intraventricular hemorrhage, subarachnoid hemorrhage, or early periventricular leukomalacia in premature infants. The ventriculomegaly is probably of prenatal origin.[20]

Diagnosis of myotonic dystrophy is supported by clinical and electromyographic examination of the mother and confirmed by molecular genetic analysis. If the infant survives, the hypotonia and severe weakness gradually improve and are no longer evident by later childhood, although motor development is delayed. The facial diplegia with ptosis, open jaw, and triangular mouth persists, giving rise to a characteristic appearance.[32,45] Many affected infants die early, even with intensive care. There is increased mortality among infants requiring greater than 30 days of ventilation, although eventual maturation of diaphragmatic musculature allows for independent ventilation in most.[13] In most patients, mental retardation or significant learning difficulties develop.[32] Unless there is a superimposed cerebral palsy syndrome from a complication of prematurity or perinatal asphyxia, most children walk by age 3 years.[45] All patients with congenital myotonic dystrophy eventually manifest the complete spectrum of features typical of adult-onset disease.

OTHER MUSCULAR DYSTROPHIES

Severe Xp21-linked dystrophin-deficient muscular dystrophy (Duchenne type) is a degenerative muscle disorder that rarely presents during the neonatal period.[54] Information is scarce on a typical phenotype during the neonatal period. Distinguishing features are an absence of arthrogryposis, high serum creatine kinase, and regeneration or degeneration on muscle biopsy. Diagnosis is made by DNA analysis and immunoelectrophoresis or immunocytochemistry.[38]

Facioscapulohumeral muscular dystrophy is an autosomal dominant disorder that usually presents during early adolescence. Although usually a fairly benign disorder, there is intrafamilial variability, and the disease can present in early infancy.[10] The responsible abnormal gene has been assigned to the subtelomeric region of chromosome 4.[38] Affected patients have a reduction in the normal number of repeats in the DNA sequence termed *D4Z4*. In normal individuals, the EcoR1-digested DNA fragment is usually larger than 28 kilobases (kb), whereas a shorter fragment of 14 to 28 kb is detected in cases of facioscapulohumeral muscular dystrophy, correlating with the smaller number of repeats.[38] In the early infantile form of the disease, facial weakness is characteristic, and the only manifestation might be partially open eyes during sleep. Progression is variable. In some cases, weakness is relatively mild, with later development of facial and shoulder girdle weakness. In other cases, there is early progressive weakness of the face, shoulder girdle, and ankle dorsiflexion, with loss of independent ambulation by late childhood. Bilateral sensorineural hearing loss is present in many cases. Retinal vascular abnormalities can also be found, which sometimes progress with exudation and retinal detachment. Creatine kinase levels are only moderately elevated. Biopsy of a proximal shoulder girdle muscle shows mild myopathic changes. Other pathologic findings include small, angular fibers; "moth-eaten" fibers; and cellular infiltrates, which can be extensive and appear inflammatory. Although steroids in general are not beneficial in this disorder, albuterol has shown some modest benefit.[41] Electromyography of an affected muscle reveals a myopathic pattern with short-duration, low-amplitude polyphasic potentials.

CONGENITAL MYOPATHIES

The congenital myopathies are primary muscle disorders that are present at birth. Although their expression might not be apparent during the neonatal period, infancy, or childhood, these myopathies are probably all genetically determined. Muscular dystrophies, inflammatory myopathies, muscle diseases caused by metabolic disorders, and inborn errors of metabolism are not included in this group. Congenital myopathies are usually characterized on the basis of their histologic and histochemical features. Although more than 30 different types of congenital myopathies have been described, most of these are rare and unlikely to represent clinically distinct entities. The four myopathies discussed here are relatively common and represent distinct clinical entities with unique histochemical findings.

Nemaline Myopathy

Nemaline myopathy is so called because of the characteristic rod bodies in muscle, which in longitudinal section appear threadlike (Fig. 40-83). They are best seen after modified Gomori trichrome staining of frozen sections, in which they appear red against a blue-green myofibrillar background.[14] The rod bodies are usually subsarcolemmal, and their numbers in muscle are variable and not correlated with the severity of the disease. However, intranuclear rods can be seen in the severe neonatal form of the disease. On electron microscopy, the rods appear to originate from the Z discs in conjunction with Z-disc thickening and streaming, and are composed of thin filament proteins, α-actinin, and actin. In addition to nemaline rods, muscle biopsy shows variations in fiber size, with a predominance of type 1 fibers, which are smaller than the type 2 fibers.

The disorder has a wide clinical spectrum. A severe congenital form presents with generalized weakness and hypotonia involving the face, bulbar, and respiratory muscles but clinically sparing the eye muscles.[57] Milder forms present during the neonatal period or early childhood. It is relatively nonprogressive and has a facioscapuloperoneal pattern of weakness. The face is long and thin; the palate is arched; and muscle bulk is poor. A relatively mild adult-onset form also exists. All variants can show preferential diaphragmatic weakness with a significant percentage requiring prolonged

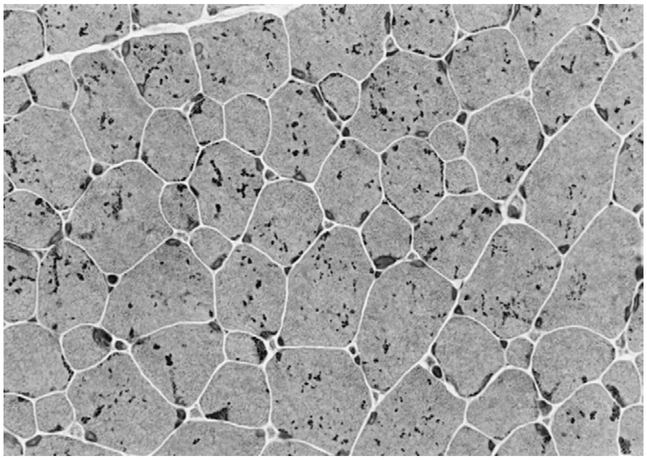

Figure 40–83. Histologic section of muscle showing nemaline myopathy. Shown are variations in fiber size. Characteristic rod bodies are seen in the muscle fibers. Low magnification. *(Courtesy of Hannes Vogel, MD, Baylor College of Medicine, Houston.)*

assisted ventilation. The severity of respiratory involvement at delivery predicts survival. Motor outcome parallels respiratory involvement in the neonatal form.[58] Cardiac involvement is rare and secondary to respiratory disease and pulmonary hypertension. Likewise, a neonatal encephalopathy is related to respiratory failure with hypoxic-ischemic injury.[58] Diagnosis is by muscle biopsy. The creatine kinase is usually normal or only slightly elevated. Electromyography in the older child usually shows myopathy, but in the newborn infant it is typically not helpful. Most cases are sporadic, although both autosomal dominant and autosomal recessive inheritance can occur. Mutations in five genes encoding for muscle thin filaments have been identified. These include α-tropomyosin (*TPM3*), β-tropomyosin (*TPM2*), α-actin (*ACTA1*), nebulin (*NEB*), and troponin T1 (*TNNT1*).[58,69] Mutations in the *TNNT1* gene on chromosome 19q13.4 cause a severe autosomal recessive form of the disease in the Amish population that usually has a fatal outcome in the second year of life.[62] There is otherwise no correlation between mutations in the same gene, mode of inheritance, and clinical severity. In addition, there is considerable intrafamilial variation in course and outcome. Sequencing of the *ACTA1* gene is clinically available.

Central Core Disease

Central core disease is an autosomal dominant disorder. Muscle biopsy reveals characteristic central cores of degenerated myofibrils in type 1 fibers, which predominate.[14] The disorder is usually mild when it presents during the neonatal period. Muscle weakness and hypotonia are usually more prominent proximally, and congenital hip dislocation is a frequent associated finding.[38] Mild delay in motor maturation occurs, and scoliosis and contractures can develop later. The gene locus responsible for almost 80% of cases has been mapped to chromosome 19q12-13.2, which is closely linked to the gene for malignant hyperthermia and the ryanodine receptor (*RYR1*).[62] All affected patients are at risk for malignant hyperthermia.

Multi-Minicore Myopathy

Multi-minicore disease is characterized by multiple small areas of sarcomeric disorganization that lack oxidative activity.[28] There is a predominance of small type 1 fibers. Four homogeneous phenotypes have been defined. The classic form presents with mild proximal weakness, joint laxity, scoliosis, and respiratory insufficiency with a rigid spine. An ophthalmoplegic form is associated with facial and generalized weakness. An early onset form may result in arthrogryposis. A slowly progressive form presents with hand amyotrophy. Cardiomyopathy may occur. Both autosomal recessive and sporadic inheritance may occur.[28] Diagnosis is by muscle biopsy and mutations in the *SEPN1* or *RYR1* gene account for many of the cases.

Myotubular Myopathy

Myotubular myopathy presenting in the neonatal period is an X-linked recessive condition and one of the most severe congenital myopathies. It is due to mutations in the myotubularin gene (*MTM1*) on chromosome Xq28. The protein tyrosine phosphorylase encoded by this gene is thought to have a vital role in normal myogenesis. The myopathy is characterized pathologically by muscle fibers that contain large central nuclei and resemble fetal myotubes (Fig. 40-84).[14] This central area also lacks myofibrils and appears as a clear area with adenosine triphosphatase staining. There is a predominance of small type 1 fibers. The appearance of the muscle is not due to a general arrest in muscle development but rather is related to a persistence of fetal cytoskeletal proteins, vimentin, and desmin, which preserve the immature central portions of the nuclei.[14]

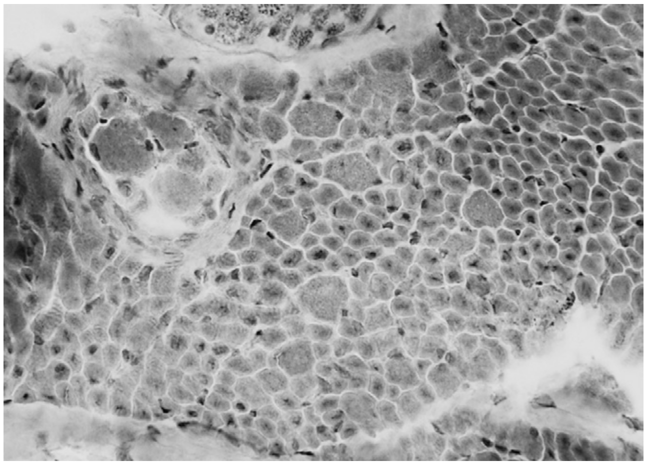

Figure 40–84. Histologic section of muscle showing myotubular myopathy. Shown are large muscle fibers with central nuclei seen primarily in small, predominantly type 1 fibers. Low magnification. *(Courtesy of Hannes Vogel, MD, Baylor College of Medicine, Houston.)*

With onset during the fetal period, there is often history of polyhydramnios. Death may occur soon after birth or within the first year of life from respiratory failure, although long-term survival is possible. Typical clinical features include generalized hypotonia with facial weakness and ophthalmoplegia. Congenital contractures may be present. Although the disease is nonprogressive in survivors, these patients remain extremely weak, wasted, and unable to sit unsupported. Female heterozygotes may exhibit early onset of limb-girdle weakness, but are usually asymptomatic.[62]

Diagnosis of the neonatal variants is initially made by muscle biopsy. Genetic analysis of the myotubularin gene is available and allows for prenatal diagnosis. The creatine kinase level is usually normal, and electromyography is not helpful.

METABOLIC AND MULTISYSTEM DISORDERS

A large number of metabolic disorders directly involve the neuromuscular system and are broadly divided into primary abnormalities of glycogen, lipid, mitochondrial, and peroxisomal metabolism.[68] Some are responsible for well-defined clinical syndromes, such as acid maltase deficiency, which causes Pompe disease, whereas others are protean in their manifestations (see Chapter 50).

Mitochondrial Myopathies

Mitochondrial myopathies are categorized according to the involved area of abnormal metabolism, as follows: (1) defects of substrate transport; (2) defects of substrate utilization and the citric acid cycle; and (3) defects of the electron transport chain and oxidative phosphorylation coupling.[68] In the newborn, defects in electron transport (respiratory chain) are those most likely to lead to prominent muscle disease. Other abnormalities of mitochondrial metabolism, such as pyruvate carboxylase and pyruvate dehydrogenase complex deficiency, are more likely to present with features of a progressive encephalopathy. The most common of the respiratory chain disorders presenting as a myopathy during the neonatal period is cytochrome-*c* oxidase deficiency.[38] Typically, the infant presents with profound generalized weakness, hypotonia, hyporeflexia, poor feeding reflex, respiratory difficulty, and lactic acidosis. Other features may include hepatomegaly, cardiomyopathy, renal tubular defects (de Toni-Fanconi syndrome), and macroglossia. Death occurs within a few months. A reversible form of cytochrome-*c* oxidase deficiency also occurs.[38] The disorder presents in a fashion similar to the severe form but improves biochemically and clinically over the next 1 to 2 years. Early diagnosis is vital to provide continuing support while improvement takes place.

A mitochondrial myopathy should be suspected in any weak infant with lactic acidosis, particularly in conjunction with multisystem involvement. The creatine kinase level can be slightly elevated, but electromyography is usually not helpful. Muscle biopsy shows nonspecific myopathic changes, ragged red fibers on Gomori trichrome staining, and an absence of histochemical staining for cytochrome-*c* oxidase. Electron microscopy of muscle fibers demonstrates lipid and glycogen accumulations and an increased number of large, abnormal-looking mitochondria. The benign and severe forms are differentiated by immunohistochemical techniques, using antibodies directed against different subunits of cytochrome-*c* oxidase. In the fatal form, there is an absence of DNA-encoded subunit VIIa, b. In the benign form, however, both this subunit and the mitochondrial DNA-encoded subunit II are absent.[38] Cytochrome-*c* oxidase deficiency in Leigh syndrome (encephalopathy and magnetic resonance imaging changes) has been recently associated with mutations of *SURF1*, a gene located on chromosome 9q34. However, mutations have not been found in patients with cytochrome-*c* oxidase without Leigh syndrome.

Disorders of Glycogen Metabolism

See also Chapter 50.

Apart from acid maltase (α-glucosidase) deficiency (Pompe disease), the autosomal recessive disorders of glycogen metabolism present only rarely during the neonatal period.[68] These rare presentations occur with debrancher enzyme deficiency, phosphorylase deficiency, and phosphofructokinase deficiency.

POMPE DISEASE (TYPE II GLYCOGEN STORAGE DISEASE)

The infantile form of Pompe disease is caused by a deficiency of acid maltase (α-glucosidase). The disorder can present during the neonatal period, although clinical onset during the second month of life is more usual.[31,38] The enzyme deficiency causes glycogen accumulation in anterior horn cells of the spinal cord and in the muscles, heart, liver, and brain. Infants present with profound generalized weakness, hypotonia, hyporeflexia, impaired awareness, heart failure, and hepatomegaly. Tongue fasciculations, a large tongue, and severe bulbar weakness are often present. The chest radiograph and electrocardiogram demonstrate cardiomegaly, short PR intervals, and giant QRS complexes. The serum creatine kinase and liver enzymes are elevated and electromyography shows combinations of denervation and myopathy, including fibrillations and small polyphasic potentials. Muscle biopsy reveals vacuoles containing glycogen, which stain with periodic acid-Schiff. The gene for the α-glucosidase enzyme protein is located on chromosome 17q23-25. Diagnosis typically is made by demonstrating the enzyme deficiency in leukocytes, lymphocytes, fibroblasts, or muscle or by demonstrating mutations in both alleles. GAA is the only gene known to be associated with Pompe disease. However, there is extensive genetic heterogeneity, and common mutations are found only in ethnic groups such as Ashkenazi Jews or the Amish in Pennsylvania. Prenatal diagnosis has been successful by demonstrating enzyme deficiency in cultured amniotic cells, linkage analysis, and mutation analysis. Prognosis is usually poor, with most infants dying within the first 6 months of life. Therapy continues to be palliative despite current efforts to develop enzyme and gene therapy.[2,31]

DEBRANCHER ENZYME DEFICIENCY (TYPE III GLYCOGEN STORAGE DISEASE)

Rarely, debrancher enzyme deficiency can present during the neonatal period with hypotonia, weakness, hypoglycemia, hepatomegaly, and liver dysfunction. Muscle biopsy shows abnormal glycogen storage, and diagnosis is established by demonstration of the debrancher enzyme deficiency.[38]

McARDLE DISEASE (TYPE V GLYCOGEN STORAGE DISEASE)

There are three different isozymes of phosphorylase (liver, brain, muscle), genes of which have been cloned and localized to different chromosomes.[63] Deficiency of the muscle enzyme on chromosome 11p13 causes McArdle disease.[38] Clinical presentation occurs typically during adolescence, with exercise intolerance, cramps, and myoglobinuria. However, the disorder shows clinical variability and rarely presents during the neonatal period.[18] Infants with infantile McArdle disease are weak and hypotonic with feeding difficulties. In some infants, the weakness is extreme, contractures are present, and the outcome fatal.[46] Even in the less severe neonatal form, the weakness is slowly progressive but without significant cranial nerve dysfunction. Muscle biopsy shows variations in fiber size, absence of phosphorylase staining, and subsarcolemmal glycogen-containing vacuoles. Unlike Pompe disease, the accumulated glycogen is not membrane bound.[14] Definitive diagnosis is made by demonstrating deficiency of the muscle isozyme or by demonstrating mutations in the phosphorylase gene. Treatment for this condition remains limited. There has been some success with high-protein diets or ingestion of sucrose before exercise.[67]

PHOSPHOFRUCTOKINASE DEFICIENCY (TYPE VII GLYCOGEN STORAGE DISEASE)

Phosphofructokinase deficiency usually presents with cramps on exercise and myoglobinuria. A severe infantile form presents during the neonatal period.[4] Affected infants exhibit hypotonia, progressive weakness, and contracture formation. Some infants have seizures, cortical blindness, and mental retardation.[68] The muscle biopsy findings are similar to those of McArdle disease, with nonmembrane-bound subsarcolemmal glycogen deposits. Diagnosis is established by demonstrating a reduction of phosphofructokinase activity biochemically and histochemically.[14]

Primary Carnitine Deficiency

Primary carnitine deficiency is caused by a deficiency in the transport of carnitine from plasma into the cells of affected tissues.[38] The disorder usually presents in early childhood with a cardiomyopathy, proximal muscle weakness, or recurrent encephalopathy. Rarely, it presents during the neonatal period with weakness, hypotonia, and cardiomyopathy. Hypoketotic hypoglycemia is a clue to diagnosis.[68] Muscle biopsy shows lipid-containing vacuoles, and serum and muscle carnitine levels are low. The carnitine transporter defect can be demonstrated in cultured fibroblasts.[38]

Peroxisomal Disorders

Peroxisomal disorders can present during the neonatal period with profound hypotonia and weakness. Signs include CNS dysfunction; facial dysmorphism, as in Zellweger syndrome; hepatomegaly; cataracts; retinopathy; calcific stippling of epiphyses; and rhizomelia.[8] These disorders are discussed in Chapter 50.

PART 7

Disorders in Head Shape and Size

Alan R. Cohen

This part focuses on conditions that result in an alteration of head size or of head shape in the newborn infant. Emphasis is on the clinical presentation, diagnostic procedures, and available treatment options.

EXAMINATION OF THE HEAD

The head is inspected for abnormalities of size and shape. The scalp is examined for the presence of a neurocutaneous signature such as a dimple, dermal sinus, hemangioma, or port wine stain. Certain mass lesions are easily detected, such as tumors of the scalp and calvaria, traumatic subperiosteal hemorrhage (the so-called cephalhematoma), and cranial dysraphic masses, such as the encephalocele.

The shape of the head is noted and the patency of the cranial sutures is ascertained. The anterior fontanelle is palpated and should be flat or slightly sunken. The anterior fontanelle is a diamond-shaped soft spot at the junction of the frontal and parietal bones, which marks the site of the future bregma, a craniometric point that denotes the junction of the metopic, coronal, and sagittal sutures. It usually closes by approximately age 18 months (range, 6 months to 2 years). It pulsates with the heartbeat and may bulge normally during crying. The mean time of closure is 16.3 months for boys and 18.8 months for girls.[2] A full or tense anterior fontanelle may signify a pathologic process associated with increased intracranial pressure. Early closure of the anterior fontanelle may be seen in microcephaly or craniosynostosis, or may be a variation of normal. The posterior fontanelle is smaller than the anterior fontanelle and bridges the parietal and occipital bones at the site of the future lambda, the craniometric point denoting the junction of the sagittal and lambdoid sutures. The posterior fontanelle usually closes by age 3 months.

The head circumference is a useful gauge of the intracranial volume, and measurement of the head circumference is of paramount importance in the neurologic examination of the newborn. A thin flexible tape measure is used to record the occipitofrontal circumference (OFC). The tape is pressed firmly against the scalp to include the most prominent portion of the occiput, which is usually at or just above the external occipital protuberance (inion) and the most prominent portion of the forehead, which is usually located just above the glabella. The OFC is plotted on a standard graph and is considered within the normal range if it is not greater than 2 standard deviations above or below the mean. The OFC provides an immediate assessment of head size and is useful for future assessment of head growth patterns. For preterm infants, gestation-adjusted age should be recorded on growth charts until 24 to 36 months.

The normal infant's OFC increases by approximately 2 cm in the first month of life and by approximately 6 cm in the first 4 months. In the healthy premature infant, there may actually be transient head shrinkage with a reduction in OFC and overriding sutures in the first days of life. This is thought to be related to water loss from the intracranial compartment.[82] This head shrinkage is maximal at approximately the third day of life, and by the second week the head circumference should be increasing.

THE SMALL HEAD

Microcephaly (Greek *mikros*, "small," *kephale*, "head") is the condition in which the size of the head, as measured by the OFC, is significantly smaller than normal. In general, microcephaly is defined as an OFC greater than two standard deviations below the mean for age and sex, although some authors use a stricter criterion of three standard deviations below the mean. Microcephaly is often, but not always, associated with intellectual retardation.

In the normal infant, the skull enlarges as a consequence of inductive pressure generated by the growing brain. Microcephaly often occurs as the consequence. *Micrencephaly* (Greek *micros*, "small," *enkephale*, "brain"), that is, the small head, is the result of a small brain. The single exception is multiple-suture craniosynostosis, the very rare disorder in which the fused skull restricts growth of the brain. The nomenclature used to categorize microcephaly has been inconsistent and confusing. On one end of the spectrum, microcephaly describes the simple finding of a small head on physical examination. On the other end, microcephaly is not a single entity, but a complex, heterogeneous group of disorders of genetic or environmental etiology characterized by abnormal brain growth.

It is helpful to categorize microcephaly as primary or secondary to distinguish disorders of brain formation from disorders characterized by destruction of already formed brain. *Primary microcephaly* describes a group of genetic or environmental insults that cause abnormalities of neuronal induction, proliferation, or migration. These insults occur sometime within the first 7 months of gestation. *Secondary microcephaly* describes a variety of insults that occur in the latter part of the third trimester or perinatal period. These insults occur after neuronal proliferation and migration and are characterized by destruction of the brain due to trauma, hypoxia-ischemia, infection, or metabolic causes. Some authors classify genetic insults as primary microcephaly and environmental insults as secondary microcephaly, but this is somewhat inaccurate because genetic and environmental factors can influence the developing brain and the already developed brain with different consequences. All classification schemes are imperfect because of overlap among the various disorders. The classification scheme here reflects both the etiology and the timing of the insult in the developing nervous system (Box 40-15).

BOX 40–15 Causes of Congenital Microcephaly

I. PRIMARY MICROCEPHALY

Disorders of brain formation; insults causing anomalies of neuronal induction, proliferation, and migration; first 7 months of gestation.

Genetic Disorders

Chromosomal anomalies

- Trisomies 13, 18, 21
- Deletion and translocation syndromes

Somatic anomalies

- Familial microcephaly (usually autosomal recessive)
- Rubinstein-Taybi syndrome
- Smith-Lemli-Opitz syndrome
- Cornelia de Lange syndrome
- Dubowitz syndrome
- Hallermann-Streiff syndrome
- Seckel syndrome
- Prader-Willi syndrome
- Aicardi syndrome
- Nijmegen breakage syndrome

Developmental Disorders (Genetic or Environmental)

Neurulation/cleavage anomalies

- Anencephaly
- Holoprosencephaly

Migrational anomalies

- Schizencephaly
- Lissencephaly
- Polymicrogyria

Environmental Disorders

Congenital infections

- Toxoplasmosis
- Rubella
- Cytomegalovirus
- Herpes simplex
- Coxsackievirus

Biochemical disorders

- Maternal diabetes mellitus
- Maternal uremia
- Maternal phenylketonuria

Environmental toxins

- Maternal malnutrition
- Hyperthermia
- Ionizing radiation
- Teratogens (phenytoin, cocaine, alcohol, carbon monoxide)

II. SECONDARY MICROCEPHALY

Destruction of already formed brain; last 2 months of third trimester or perinatal period.

Trauma
Anoxia
Infections
Metabolic disorders

III. CRANIOSYNOSTOSIS (MULTIPLE SUTURES)

Primary Microcephaly

See also Part 1 of this chapter.

Primary microcephaly describes a heterogeneous group of disorders resulting from an insult early in embryologic development that interferes with neuronal development or migration (Fig. 40-85). This broad group of disorders may have a genetic or an environmental etiology.

GENETIC DEFECTS

Primary microcephaly may occur as an isolated insult to the central nervous system or may be seen in association with chromosomal abnormalities or as a part of other well-defined multiorgan genetic syndromes. Genetic forms of primary microcephaly may be autosomal recessive, autosomal dominant, or X-linked. Of the genetic forms, autosomal recessive transmission is the most common. Like other recessive disorders, this condition occurs with increased prevalence in geographic regions with high consanguinity. Investigators have been able to study consanguineous families with homozygosity mapping to localize recessive traits.[48] Since 1998, five autosomal recessive loci for microcephaly have been mapped by molecular geneticists collaborating with clinicians working in regions where consanguinity is common.[55] Autosomal dominant microcephaly has been observed in families, often associated with normal intelligence or only mild cognitive impairment.

NEURULATION AND CLEAVAGE ANOMALIES

Anencephaly is the most devastating of all the dysraphic malformations, and occurs as a consequence of failure of the anterior neural tube to close. The insult occurs early in embryogenesis, before day 26 of gestation. Both cerebral hemispheres are absent, as is the cranial vault (Fig. 40-86). Anencephaly is a lethal condition. Infants are either stillborn or live for only a few days. The incidence of anencephaly has been decreasing.

Holoprosencephaly occurs as a consequence of failure of the prosencephalon, or embryonic forebrain, to separate and form paired telencephalic hemispheres. The hemispheres are normally cleaved at 33 days' gestation, so the insult causing holoprosencephaly must occur early. Holoprosencephaly is usually sporadic, but an autosomal dominant familial variant has been reported. The long arm of chromosome 7 (7q) is thought to be the genetic locus for holoprosencephaly.[7] Holoprosencephaly is caused by mutations in the sonic hedgehog gene *(SHH)* and other genes located on chromosome 7q. The cleavage defects produce a clinical picture of varying severity. In the most complete form, *alobar holoprosencephaly*, there is a single hemisphere of the brain and a single midline prosencephalic ventricle. Median facial defects range from a single midline eye and rudimentary nose to orbital hypotelorism, flattening of the nose, cleft lip and palate, and trigonocephaly (triangular forehead with vertical ridge along metopic suture). Neurologic findings include mental retardation, seizures, poor temperature control, and a variety of neuroendocrine disorders related to dysfunction of the anterior and posterior pituitary gland. Less severe clinical forms of the disorder include *semilobar holoprosencephaly* and *lobar holoprosencephaly,* in order of decreasing severity (Fig. 40-87).

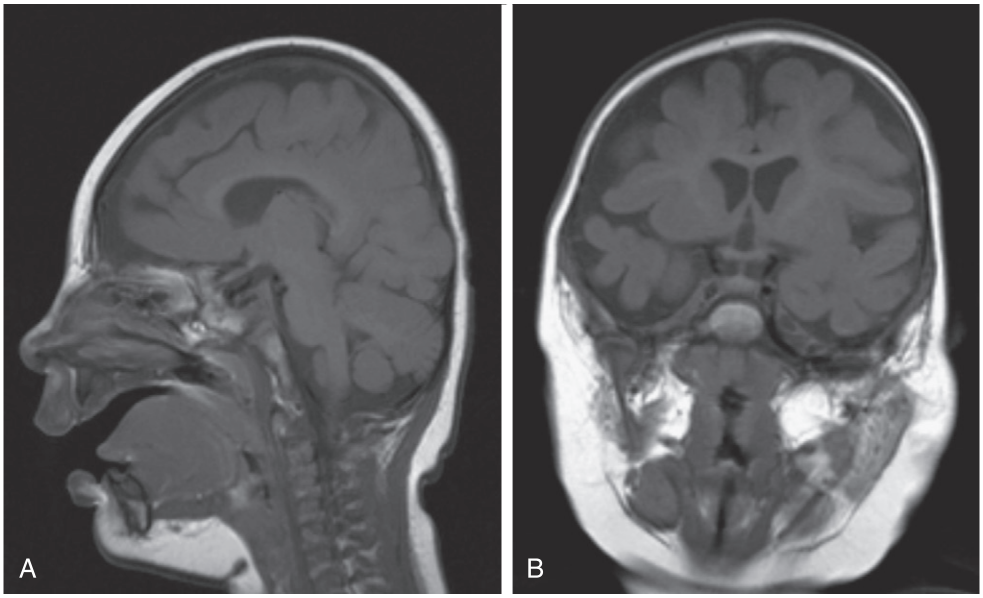

Figure 40–85. Primary microcephaly. **A**, T1-weighted sagittal magnetic resonance image. **B**, T1-weighted coronal MRI.

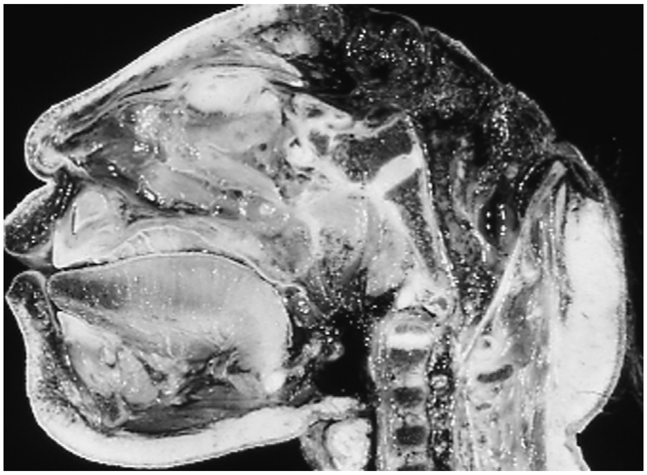

Figure 40–86. Anencephaly.

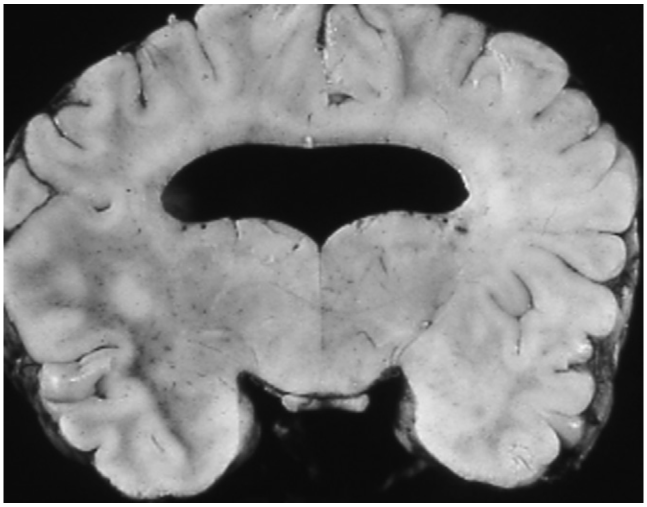

Figure 40–87. Semilobar holoprosencephaly, coronal specimen.

Other genetic causes of primary microcephaly include disorders of karyotype, including trisomies, deletions, and translocation syndromes. Among the common chromosomal abnormalities are trisomies 21, 18, and 13. Primary microcephaly may be a feature of numerous somatic disorders with normal karyotypes, including Rubinstein-Taybi syndrome, Smith-Lemli-Opitz syndrome, Cornelia de Lange syndrome, and Hallerman-Streiff syndrome (see Box 40-15). In these syndromes, characteristic dysmorphic features and patterns of other organ involvement help establish the diagnosis.

MIGRATIONAL ANOMALIES

See Part 1 of this chapter.

Neuronal migration is a radial and tangential process by which nerve cells move from their progenitor cell origin in the ventricular zone and basal forebrain to their final destination in the cerebrum. The cerebral cortex forms as the result of neuronal migration, and anomalous gyral formation is the signature finding in all migrational disorders (Fig. 40-88). Because of this cortical disruption, seizures are the most common clinical manifestation of migrational disorders. The morphologic abnormality in *schizencephaly* is a cleft in the cerebral hemisphere, which may be unilateral or bilateral, open-lipped (walls of the cleft separated, often associated with enlargement of the lateral ventricles; Fig. 40-89) or closed-lipped. In *lissencephaly* (agyria, or “smooth brain”), the cerebral hemispheres have few or no gyri (Fig. 40-90). In *polymicrogyria*, the gyri are too numerous and too small, with a proliferation of secondary and tertiary sulci. The appearance of the cortical surface has been likened to that of a wrinkled chestnut kernel (Fig. 40-91). *Neuronal heterotopias* (brain warts) are the least severe of the migrational disorders and may stand alone or occur in association with other disturbances of migration. Agenesis of the corpus callosum,

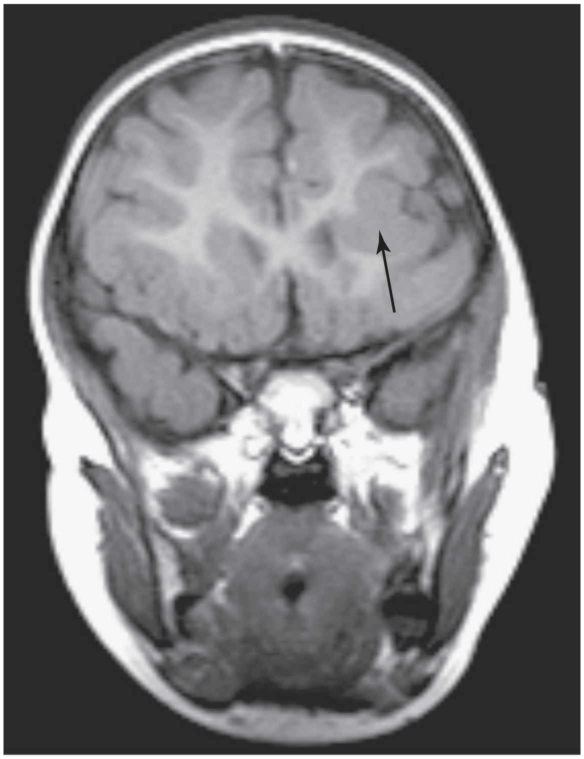

Figure 40–88. Cortical dysplasia. T1-weighted coronal magnetic resonance image shows left perisylvian cortical thickening extending to the ventricle *(arrow)*.

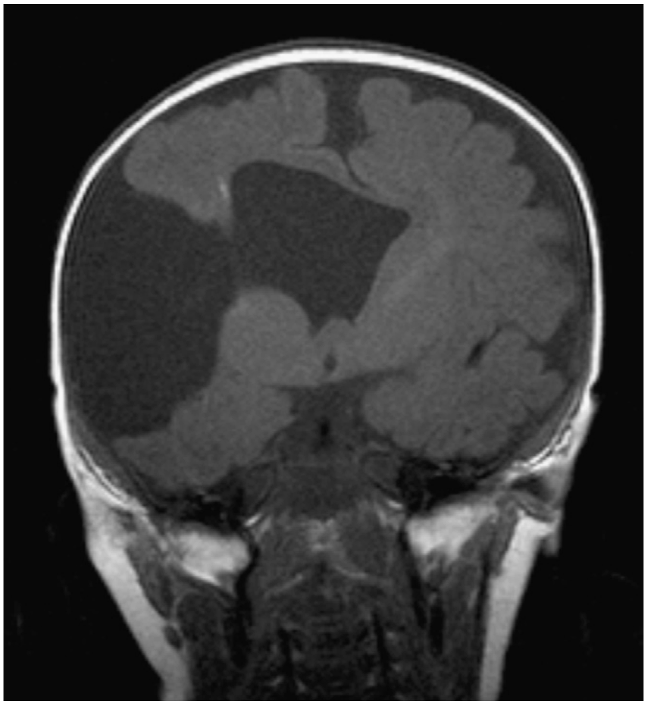

Figure 40–89. Open-lipped schizencephaly. T1-weighted coronal magnetic resonance image shows large open cleft communicating with the right lateral ventricle and absence of the septum pellucidum.

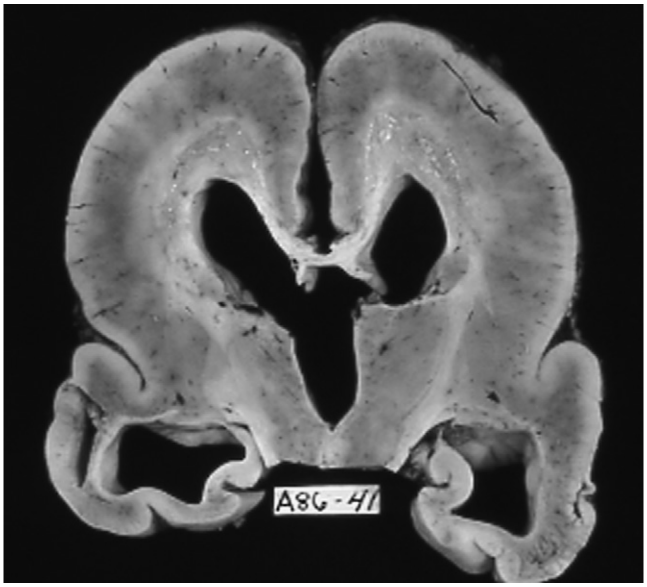

Figure 40–90. Lissencephaly, coronal specimen.

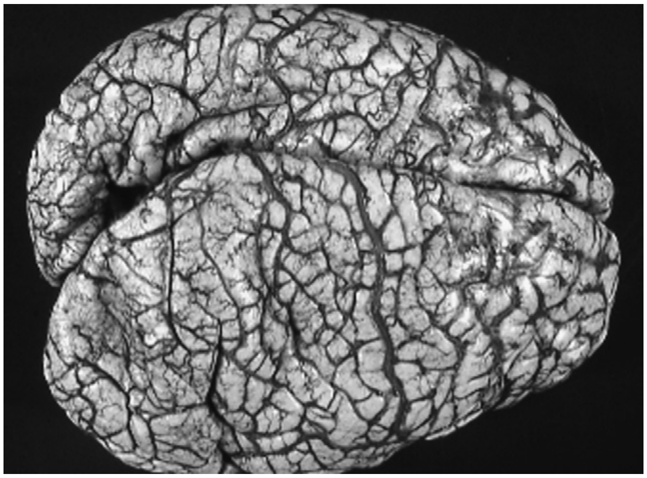

Figure 40–91. Polymicrogyria.

partial or complete, is a relatively common accompaniment in disorders of neuronal migration (Fig. 40-92). The corpus callosum is the largest of the interhemispheric commissures, and its absence may be seen in association with other midline defects, such as absence or hypoplasia of the septum pellucidum, the thin partition that divides the anterior portion of the lateral ventricles (Fig. 40-93). The triad of agenesis of the septum pellucidum, optic nerve hypoplasia, and pituitary abnormalities is called *septo-optic dysplasia,* or *DeMorsier syndrome.* Agenesis of the corpus callosum associated with cortical and subependymal gray matter heterotopias and chorioretinal lacunae was initially described by the French neurologist Jean Aicardi in 1965 *(Aicardi syndrome)*.[1] This disorder, seen only in girls, is characterized by microcephaly, profound mental retardation, and seizures in the form of infantile spasms.

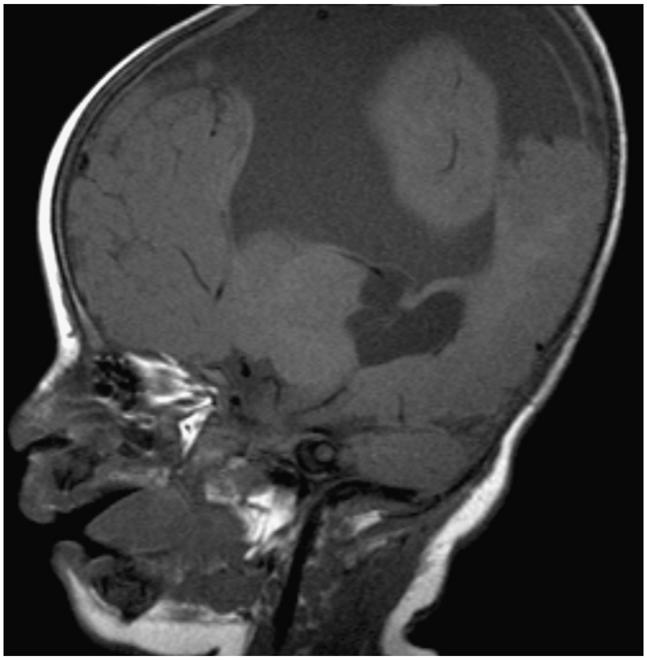

Figure 40–92. Agenesis of the corpus callosum. T1-weighted sagittal magnetic resonance image also demonstrates absence of the septum pellucidum and a large midline cerebrospinal fluid collection.

CONGENITAL INFECTIONS

See also Chapters 23 and 39.

The developing nervous system is susceptible to a variety of in utero infections. Implicated agents are collectively referred to by the acronym *TORCH syndrome* (*t*oxoplasmosis, *r*ubella, *c*ytomegalovirus, and *h*erpes simplex virus; Fig. 40-94).

BIOCHEMICAL DISORDERS

Several maternal metabolic disorders such as diabetes mellitus and uremia are associated with congenital primary microcephaly. Untreated phenylketonuria in an asymptomatic mother may be associated with microcephaly in a nonphenylketonuric infant.[49,50] Maternal malnutrition and hypertension are associated with intrauterine growth restriction and microcephaly. Teratogenic agents such as phenytoin, cortisone, cocaine, alcohol, isotretinoin, and carbon monoxide can produce microcephaly along with disorders of neuronal induction and migration. Maternal exposure to ionizing radiation has been implicated as a cause of congenital microcephaly, with earlier insults associated with more severe cases.[54]

RADIAL MICROBRAIN AND MICRENCEPHALY VERA

As our understanding of the timing of neuronal proliferation has improved, another scheme for classifying micrencephaly has been proposed. Two subgroups of micrencephaly have been postulated: *radial microbrain* and *micrencephaly vera*. This scheme is based on the work of Rakic,[63] who proposed a radial unit model to explain the major ontogenetic development of the cerebral cortex. Rakic suggested that the ependymal layer of the embryonic cerebral ventricle consists of proliferative units whose cytoarchitectonic output is translated to the expanding cerebral cortex along radial glial guides. Early symmetric division of stem cells creates these proliferative units, which behave as organized cylindrical columns containing neurons. Later asymmetric division of stem cells causes the proliferative units to enlarge, with increased numbers of neurons. Subsequent migration of the proliferative units together as columns along radial glia explains the evolution of the cerebral cortex from the primitive ventricular zone.

Radial microbrain and micrencephaly vera are disorders of micrencephaly related to impaired neuronal proliferation,

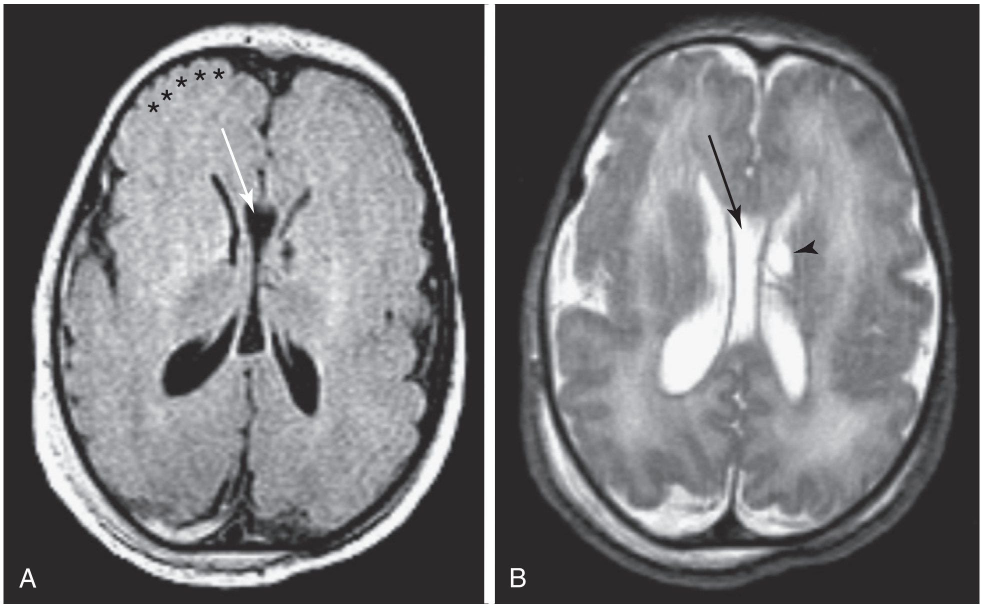

Figure 40–93. Zellweger syndrome, a peroxisomal disorder affecting the brain, kidneys, and liver. **A**, Fluid-attenuated inversion recovery (FLAIR) axial magnetic resonance image (MRI). **B**, T2-weighted axial MRI. Note the multiple migrational abnormalities including polymicrogyria (*asterisks* in **A**), subependymal cysts (*arrowhead* in **B**), cortical dysplasia, and ventricular anomalies, including a cavum septi pellucidi and cavum vergae (*arrow* in **A** and **B**).

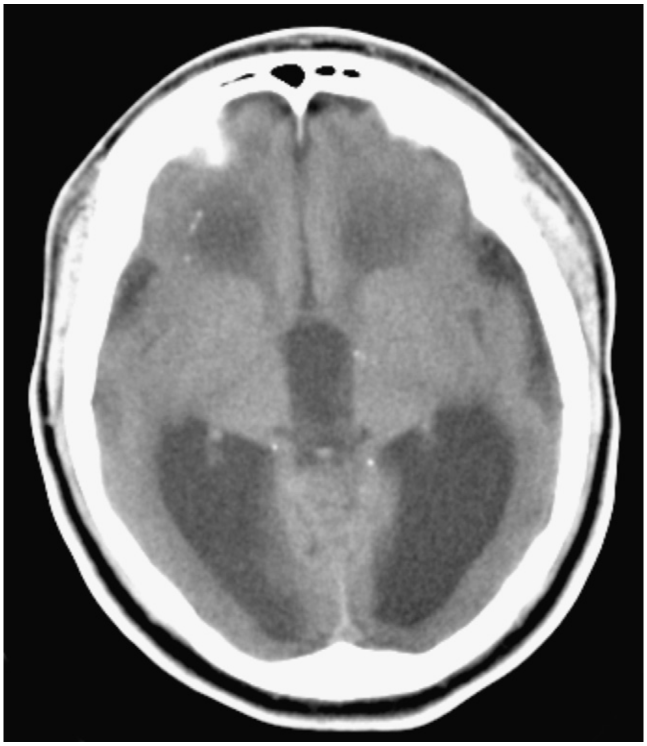

Figure 40–94. Congenital toxoplasmosis. Noncontrast computed tomography scan shows ex vacuo hydrocephalus and periventricular calcifications.

and would be categorized as forms of primary microcephaly in the conventional classification scheme. *Radial microbrain* is a rare condition described in seven cases by Evrard and colleagues,[31] in which the brain is extremely small with normal gyri and normal cortical lamination. The brain can be as small as 16 g at term (the normal newborn brain is 350 g), and in the reported cases, death has occurred in the first month. Radial microbrain is considered a genetic disorder, most likely with autosomal recessive inheritance. The pathologic finding is a marked reduction in the number of cortical neuronal columns (proliferative units), but a normal number of neurons per column. The reduced number of columns with preservation of columnar size suggests that the insult occurs early in the embryonic phase of neuronal proliferation.

Micrencephaly vera (true micrencephaly) describes a heterogeneous disorder in which the brain is well formed with a simple gyral pattern and small, but not as small as the radial microbrain. Pathologically, the number of cortical neuronal columns is normal, but the size of the columns is small because of a reduced number of neurons per column. The timing of the embryologic insult is later than that for radial microbrain, most likely between the 6th and 18th weeks of gestation. Micrencephaly vera is not a single entity and may be caused by genetic or environmental abnormalities. The distinction between radial microbrain and micrencephaly vera is of particular interest to investigators studying neuronal proliferation and the evolution of human cerebral neocortex from progenitor cells lining the embryologic ventricle.

Secondary Microcephaly

Secondary microcephaly occurs after an insult to the already developed brain. Thus, secondary microcephaly arises after neuronal induction, proliferation, and migration, typically from disorders in the last 2 months of the third trimester of pregnancy or in the perinatal period. The causes of secondary microcephaly are multifactorial and include trauma, hypoxia-ischemia, metabolic disorders, and infection (Fig. 40-95).

Craniosynostosis

Craniosynostosis, or premature fusion of one or more of the sutures of the skull, is discussed later in this chapter. Craniosynostosis causes microcephaly only rarely, when there has been premature fusion of multiple sutures. In this setting, the skull restricts growth of the brain and the infant may display irritability, lethargy, and vomiting as manifestations of increased intracranial pressure.

Evaluation and Treatment of the Small Head

A thorough history is obtained and serial measurements of the head circumference are recorded. The head circumference of both parents is measured. Laboratory investigation is tailored by the history and examination. If a congenital infection is suspected, TORCH titers can be collected from the mother and child. If a genetic disorder is suspected, karyotyping or genetic mapping can be carried out. Imaging of the brain is usually performed with computed tomography (CT) or magnetic resonance imaging (MRI). In general, CT is the optimal study to examine the bone, such as in selected cases of craniosynostosis. MRI is the optimal study to examine the architecture of the brain. Congenital microcephaly is frequently associated with significant mental retardation, sometimes with cerebral palsy and epilepsy. Appropriate supportive care as well as genetic and family counseling are important features in the management of congenital microcephaly.

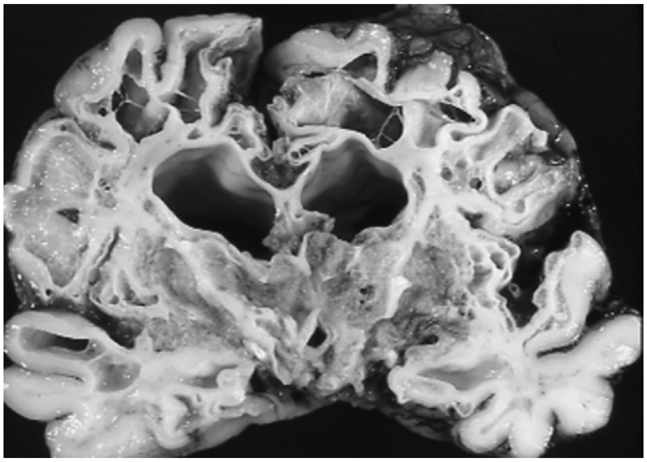

Figure 40–95. Secondary microcephaly with destruction of previously formed brain by a hypoxic-ischemic insult.

THE LARGE HEAD

Macrocephaly (Greek *makros*, "large," *kephale*, "head") is the term used to describe a large head. It is not a single disease entity, but a finding on physical examination from a variety of causes. Conventionally, macrocephaly is defined as a head circumference greater than 2 standard deviations above the mean. Evaluation should be undertaken if a single measurement of the head circumference is significantly abnormal on the growth chart or if the head circumference crosses one or more percentiles on serial examinations.

There are three general etiologies for congenital macrocephaly (Box 40-16): enlargement of the brain itself (macrencephaly), enlargement of the cerebrospinal fluid (CSF) spaces (e.g., hydrocephalus), and the presence or enlargement of other structures (e.g., brain tumor, brain abscess, intracranial hematoma).

BOX 40–16 **Causes of Congenital Macrocephaly**

I. ENLARGEMENT OF THE BRAIN (MACRENCEPHALY)

Isolated Macrencephaly
Familial (autosomal dominant or recessive)
Sporadic
Unilateral macrencephaly (hemimegalencephaly)

Macrencephaly and Growth Disorders
Beckwith-Wiedemann syndrome
Sotos syndrome (cerebral gigantism)
Achondroplasia

Neurocutaneous Syndromes
Neurofibromatosis type 1
Sturge-Weber disease
Tuberous sclerosis

Chromosomal Disorders
Fragile X syndrome
Klinefelter syndrome

Degenerative Disorders
Alexander disease
Canavan disease

Metabolic Disorders
Tay-Sachs disease
Generalized gangliosidoses

II. ENLARGEMENT OF THE CEREBROSPINAL FLUID SPACES

Hydrocephalus
Benign external hydrocephalus
Hydranencephaly
Dandy-Walker malformation
Arachnoid cyst

III. PRESENCE OR ENLARGEMENT OF OTHER STRUCTURES

Neoplasms
Vascular lesions (vein of Galen malformation)
Trauma (subdural hematoma, hygroma)
Infection (brain abscess, subdural empyema, effusion)

Macrencephaly

Macrencephaly (Greek *makros*, "large," *enkephalos*, "brain") literally describes enlargement or overgrowth of the brain. The term is synonymous with *megalencephaly* (Greek *megas*, "large," *enkephalos*, "brain"). Macrencephaly itself is not a single disorder. Instead, it represents a heterogeneous group of disorders resulting from abnormal proliferation of brain tissue or excessive storage of brain metabolites leading to a large or "heavy" brain. Whereas the normal infant brain weighs approximately 350 g at birth, the macrencephalic brain may weigh up to twice that amount. The neuropathologic substrates of macrencephaly have not been fully characterized. Aside from the obviously enlarged head, physical findings are varied, ranging from completely normal results on neurologic examination to severe seizures and mental retardation. The spectrum of macrencephaly is discussed in the following sections.

ISOLATED MACRENCEPHALY

Isolated macrencephaly can be familial or sporadic. Familial macrencephaly is an inherited disorder in which the head size of an otherwise normal infant is excessively enlarged. A clue to the diagnosis is the finding of an abnormally enlarged head in one or both parents. The child is born with an enlarged head that tends to remain enlarged and can sometimes grow at a rapid rate. Most children are neurologically normal or near-normal. In true familial macrencephaly, the only finding on neuroimaging studies is enlargement of the brain. Familial macrencephaly is thought to be related to another condition, so-called benign external hydrocephalus of infancy, in which there is enlargement of the extracerebral subarachnoid space (see "External Hydrocephalus," later), and one wonders whether these are really variants of the same condition. Most cases of familial macrencephaly are characterized by autosomal dominant inheritance. Infants with the rare autosomal recessive variant are more likely to be neurologically impaired, with mental retardation, seizures, and motor delay. Sporadic macrencephaly is used to describe isolated macrencephaly in an infant whose parents have normal head circumferences and for whom there is no other demonstrable etiology for brain enlargement.

MACRENCEPHALY AND GROWTH DISORDERS

Macrencephaly is sometimes associated with generalized disorders of growth. The syndrome of cerebral gigantism was described by Sotos and colleagues in 1964.[76] *Sotos syndrome* is characterized by macrencephaly along with macrosomia, enlargement of the hands and feet, and poor coordination.[28] Macrencephaly begins prenatally in 50% of cases and by 1 year in all affected children. Mental retardation is variable, but behavioral problems are significant and there is often delay in motor milestones. Midline intracranial anomalies have been described on MRI, including agenesis of the corpus callosum and septum pellucidum, as well as hypoplasia of the cerebellar vermis. Ventriculomegaly is common, with prominence of the trigone and occipital horns.[74]

Macrencephaly may be seen in association with macroglossia, macrosomia, visceromegaly, omphalocele, exophthalmos, and neonatal hypoglycemia. This condition, the *Beckwith-Wiedemann syndrome*, was described independently by John Bruce Beckwith, an American pathologist, and

Hans-Rudolf Wiedemann, a German pediatrician. Craniofacial features include a prominent occiput, large anterior fontanelle, and a ridge along the metopic suture.[40] Mental retardation, if present, is thought to be more likely a consequence of uncontrolled neonatal hypoglycemia than of malformation of the brain. Children with Beckwith-Wiedemann syndrome have an increased incidence of Wilms tumor, adrenal cortical carcinoma, and hepatoblastoma.

Achondroplasia is the most common form of dwarfism. Head enlargement in achondroplasia is sometimes a consequence of hydrocephalus and sometimes a consequence of true macrencephaly. Affected children have frontal bossing with a flattened nasal bridge, mild midface hypoplasia, as well as a short cranial base and small foramen magnum. True compression of the brainstem and cervical spinal cord are infrequent but potentially devastating. Achondroplastic children usually have normal intelligence.

NEUROCUTANEOUS SYNDROMES

The neurocutaneous syndromes, or *phakomatoses*, are each characterized in part by abnormal cellular proliferation in the central nervous system. Several of the neurocutaneous syndromes are associated with macrencephaly. *Neurofibromatosis type 1 (NF-1)* is an overgrowth syndrome that can be associated with neonatal or infantile macrencephaly. Distortion of cortical architecture has been reported, along with spongiform hamartomatous changes in the white matter, basal ganglia, brainstem, and cerebellum. Glial neoplasms are common, and optic glioma can be seen in neonates. Using quantitative MRI, Cutting and associates[24] found that brains of patients with NF-1 are significantly larger than normal, with a prevalence of macrencephaly in NF-1 of approximately 50%.

Macrencephaly may be a part of other neurocutaneous disorders, but is seen with less frequency. The *Sturge-Weber syndrome* (encephalotrigeminal angiomatosis) is a sporadic phakomatosis characterized by a facial port wine stain (nevus flammeus) and leptomeningeal vascular proliferation with cerebral cortical calcification, usually in the parietal and occipital regions. Ocular manifestations include glaucoma and buphthalmos (Greek “ox eye,” also called *hydrophthalmia*: enlargement of the eye due to congenital glaucoma). Neurologic manifestations include seizures (which may be medically refractory), focal deficits of visual, language, or motor function, and developmental delay with learning disorders and mental retardation.

Tuberous sclerosis (Bourneville syndrome) is an autosomal dominant disorder affecting skin (facial angiofibromas, subungual fibromas, ash leaf spots, shagreen patches), eye (retinal hamartomas, astrocytomas), viscera (cardiac rhabdomyomas, renal angiomyolipomas, and cysts), and brain. Neurologic manifestations are characterized by the abnormal proliferation of neurons and glia. Neuropathologic findings include cortical tubers, subependymal nodules, and, occasionally, subependymal giant cell astrocytomas that can obstruct the cerebral ventricles at the foramina of Monro (Fig. 40-96). The neurologic presentation is one of seizures, cognitive impairment, and behavioral disorders.

CHROMOSOMAL DISORDERS

Fragile X syndrome is second to Down syndrome as a genetic cause of mental retardation. The genetic mutation is thought to involve unstable trinucleotide repeats, with a fragile site at the tip of the long arm of the X chromosome. The disorder predominantly affects boys. Craniofacial manifestations include macrocephaly with a prominent jaw, a long, narrow face with a prominent forehead, and prominent ears. *Klinefelter syndrome* (genotype 47 XXY) has been reported in association with macrencephaly.[13] Boys with Klinefelter syndrome may have normal intelligence, although behavioral disorders are common, along with minor disturbances in learning and development.

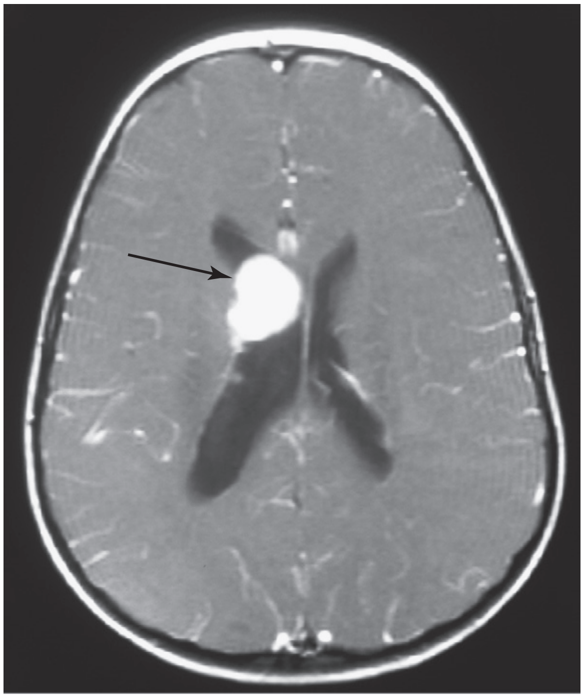

Figure 40–96. Tuberous sclerosis. An enhancing subependymal giant cell astrocytoma *(arrow)* is obstructing the right foramen of Monro, causing hydrocephalus.

DEGENERATIVE DISORDERS

Canavan disease is named for Myrtelle Canavan, an American neurologist who first described the disorder in 1931. It is an autosomal recessive leukodystrophy caused by mutation in the gene for the enzyme aspartoacylase, leading to accumulations of *N*-acetylaspartate and deterioration of the white matter, predominantly affecting individuals of eastern European (Ashkenazi) Jewish descent. Canavan disease is a progressive cerebral spongiform degenerative disorder characterized by vacuolization of the deep layers of the cortex and the subcortical white matter. The infantile form presents in the first few months of life with hypotonia and macrencephaly. The natural history is one of mental retardation, loss of acquired motor skills, hypotonia, and acquired blindness, with death usually occurring by 3 to 4 years of age. The diagnosis can be confirmed on urine organic acid analysis by the finding of elevated levels of *N*-acetylaspartate. Treatment is supportive.

Alexander disease is a sporadic progressive leukodystrophy described by W. Stewart Alexander, a 20th century English pathologist. Three clinical syndromes have been described: the infantile, juvenile, and adult forms. The infantile form of the disease is the most common and is characterized by macrocephaly, developmental delay, spasticity, and seizures. Onset is at age 6 months on the average, but clinical manifestations may be seen shortly after birth. The predominant feature on cranial MRI is impairment of the white matter anteriorly, with the posterior white matter affected later. The disorder is progressive, usually leading to death within the first decade, and treatment is supportive. The pathologic finding is macrencephaly with Rosenthal fibers—spherical eosinophilic intracytoplasmic inclusion bodies in the astrocytes. Alexander disease results from a mutation in the gene for glial fibrillary acidic protein, an intermediate filament protein found in the Rosenthal fibers.[11]

METABOLIC DISORDERS

Gangliosidoses are marked by the accumulation of gangliosides (glycosphingolipids) in cellular lysosomes secondary to enzymatic deficiency states. The hallmark of the gangliosidoses is *Tay-Sachs disease* (infantile GM2 gangliosidosis), a fatal autosomal recessive disorder. Like Canavan disease, it predominantly affects individuals of Ashkenazi Jewish descent. It is caused by a deficiency of the enzyme hexosaminidase A, which leads to accumulation of the lipid GM2 ganglioside in the central nervous system. Clinical features include macrencephaly, cherry-red spots on the retinal maculae, weakness, psychomotor retardation, seizures, and blindness, leading to death in early childhood. The macular findings were described by British ophthalmologist Warren Tay in 1881 and the clinical and pathologic findings were described by American neurologist Bernard Sachs in 1887.

Macrencephaly may also be seen with other GM1 and GM2 gangliosidoses. *Sandhoff disease* is a variant of Tay-Sachs disease in which GM2 ganglioside accumulates because of deficiency of both hexosaminidase A and B. The clinical manifestations are similar to those of Tay-Sachs disease, with the addition of visceromegaly.

Enlargement of the Cerebrospinal Fluid Spaces

BACKGROUND

Macrocephaly related to enlargement of the CSF spaces occurs in relation to hydrocephalus or one of its variants. *Hydrocephalus* (Greek *hydro*, “water,” *kephale*, “head”) represents a pathologic accumulation of intracranial CSF usually, but not always, within the cerebral ventricles. The rate of formation of CSF for children and adults is approximately 0.3 mL/min, or 20 mL/h.[23,71] The rate of formation is lower for premature infants. Most of the CSF is produced in the ventricles by the choroid plexus in an energy-dependent active transport process. Approximately 10% to 20% of CSF production is extrachoroidal, coming from the substance of the brain and spinal cord.[69] The total volume of CSF in the newborn is approximately 50 mL, increasing to approximately 150 mL in the adult, with approximately 25 mL contained in the ventricles and the remainder in the subarachnoid space surrounding the brain and spinal cord.

Choroid plexus is present in each of the four ventricular chambers, and CSF flows from the lateral ventricles into the third ventricle through the paired intraventricular foramina of Monro, and from the third ventricle to the fourth ventricle through the narrow aqueduct of Sylvius. CSF exits the fourth ventricle through the foramina of Magendie and Luschka and circulates through the subarachnoid space, to be reabsorbed into the venous system in the arachnoid villi and pacchionian granulations, microtubular evaginations of the subarachnoid space in the venous sinuses. The granulations are most prominently located in the parieto-occipital region of the superior sagittal sinus.

In general, symptomatic hydrocephalus may develop from an imbalance between the rate of CSF formation and absorption. In practice, symptomatic hydrocephalus almost always results from an impairment in the circulation or absorption of CSF. The sole exception to this is the choroid plexus papilloma, a benign tumor which usually occurs in the atrium of the lateral ventricle in children and causes hydrocephalus in association with overproduction of CSF.

Hydrocephalus may be classified as *obstructive* or *ex vacuo*. Ex vacuo hydrocephalus, related to a reduction in the volume of cerebral tissue due to malformation or atrophy, does not cause macrocephaly. For purposes of this discussion, we consider only obstructive hydrocephalus, which is almost always related to impairment in the circulation or absorption of CSF. Obstructive hydrocephalus may be further subdivided based on the location of the obstruction. A blockage in the ventricular system that prevents CSF from entering the subarachnoid space causes noncommunicating hydrocephalus (e.g., aqueductal stenosis, atresia of the foramina of Monro, intraventricular neoplasm). In *noncommunicating hydrocephalus,* there is enlargement of the ventricular chambers rostral to the site of obstruction. A blockage outside the ventricular system that permits the ventricular CSF to communicate with the subarachnoid space but prevents absorption into the venous system causes *communicating hydrocephalus* (e.g., subarachnoid hemorrhage, meningitis).

Hydrocephalus may also be classified as congenital or acquired. Examples of congenital hydrocephalus include aqueductal stenosis, Dandy-Walker malformation, Chiari II malformation, and X-linked hydrocephalus. Examples of acquired hydrocephalus include neoplasm, posthemorrhagic hydrocephalus, and postmeningitic hydrocephalus. No classification scheme is perfect, and there is overlap among the different categories. For example, aqueductal stenosis may be congenital or acquired. In approximately 15% of cases, hydrocephalus may be idiopathic, with no definitive congenital or acquired etiology discernible.[45]

The clinical presentation of hydrocephalus depends on the status of the cranial sutures. In the newborn with open cranial sutures, macrocephaly is the presenting sign. In children over the age of 2 years, hydrocephalus usually presents with signs of increased intracranial pressure. Infantile hydrocephalus may be associated with rapid head growth, and charting may show the head circumference crossing percentiles. The fontanelles become full and tense even when the child is upright, and the cranial sutures become split. In the newborn, the cranial sutures can sometimes be slightly split in the absence of a pathologic process. A useful sign for increased intracranial pressure, usually due to hydrocephalus, is splaying of the squamosal suture, which runs horizontally above the ear between the temporal and parietal bones.

In advanced cases of hydrocephalus, the forehead is prominent, or bossed, the hair is sparse, and the skull is thin. Percussion of the head can yield a "cracked pot" sound (Macewen sign). If the cortical mantle is less than 1 cm in thickness, transillumination can demonstrate the pathologic accumulation of CSF. Unilateral or bilateral esotropia may result from paresis of the abducens nerve (cranial nerve VI), which has the longest course of all the cranial nerves. The "setting sun" sign is characterized by conjugate downward deviation of the eyes such that the sclera is seen above the iris, and is due to hydrocephalic compression of the vertical gaze center in the mesencephalic tectum. Papilledema is seen in older children and adults but is rare in children, likely because of the open cranial sutures. The presence of a prominent occipital shelf with a high-riding external occipital protuberance suggests a posterior fossa cyst or the Dandy-Walker malformation (cystic transformation of the fourth ventricle).

The simplest and safest of the neurodiagnostic imaging studies is ultrasonography (US). Cranial CT and MRI provide more anatomic detail. Prenatal imaging can be performed with US and, more recently, with MRI (Fig. 40-97).

Several etiologies of hydrocephalus in the newborn are discussed in the following sections.

AQUEDUCTAL STENOSIS

Stenosis of the aqueduct of Sylvius may be congenital or acquired and accounts for approximately 10% of cases of pediatric hydrocephalus. The cerebral aqueduct is a narrow, ependyma-lined conduit that connects the third ventricle with the fourth ventricle. At birth, the aqueduct measures approximately 0.5 mm in diameter and 3 mm in length.[30]

Stenosis of the aqueduct produces noncommunicating hydrocephalus, with enlargement of the lateral and third ventricles but a normal-sized fourth ventricle on neuroimaging studies (Fig. 40-98). Congenital aqueductal stenosis can be accompanied by forking, or branching of small aqueductal channels. Membranous obstruction of the aqueduct can result from a thin ependymal veil, often at the distal portion of the aqueduct. Aqueductal gliosis may follow perinatal hemorrhage or infection. Viral infections may cause aqueductal stenosis, and some experimental models of aqueductal stenosis are virally induced. In X-linked hydrocephalus (Bickers-Adams syndrome), aqueductal stenosis is accompanied by mental retardation and flexion-adduction abnormalities of the thumbs.[8] This disorder is caused by a mutation in the gene encoding the L1 cellular adhesion molecule, a glycoprotein at the cell surface mediating neural cell recognition.[44] Acquired aqueductal stenosis can occur as the consequence of a neoplasm. Characteristically, the tumor is a low-grade astrocytoma of the quadrigeminal plate (tectal glioma).[73] Occasionally, nontumoral stenosis of the aqueduct can occur in children with neurofibromatosis type 1.[77]

DANDY-WALKER MALFORMATION

See also Part 1 of this chapter.

The *Dandy-Walker malformation* consists of cystic transformation of the fourth ventricle, partial or complete agenesis of the cerebellar vermis, and enlargement of the posterior cranial fossa with upward displacement of the torcular herophili, transverse sinuses, and tentorium (Fig. 40-99). Enlargement of the supratentorial ventricular system may be present at birth or may develop over time. The malformation occurs in approximately 1 in 25,000 live births and is more frequent in

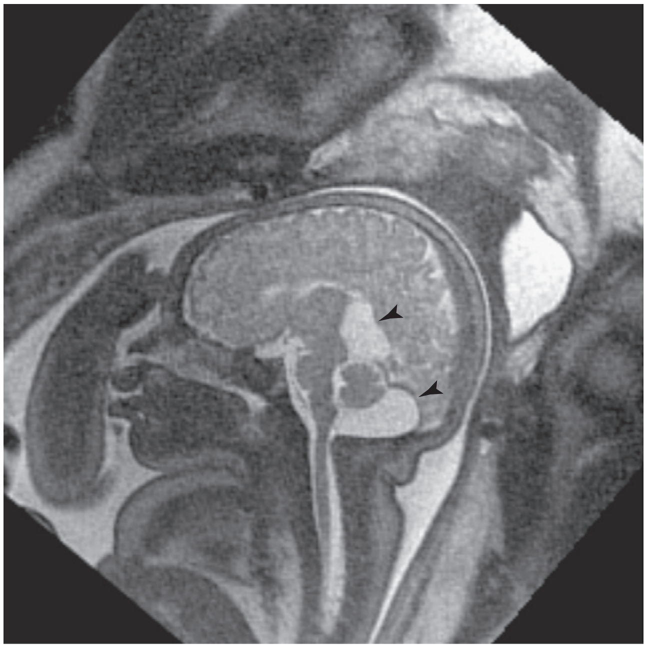

Figure 40–97. Fetal magnetic resonance image. Intrauterine sagittal view of the brain showing a quadrigeminal plate arachnoid cyst and a large cisterna magna *(arrowheads)*.

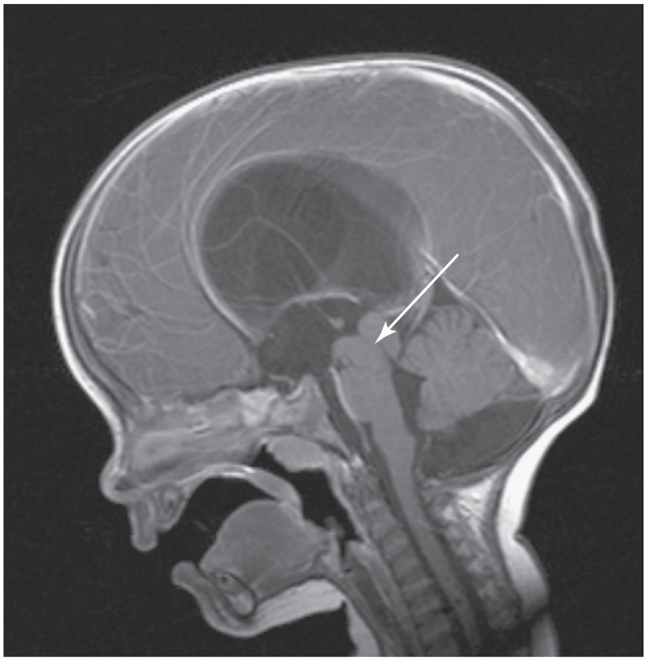

Figure 40–98. Aqueductal stenosis. T1-weighted sagittal magnetic resonance image shows noncommunicating hydrocephalus secondary to stenosis of the aqueduct of Sylvius *(arrow)*. The lateral and third ventricles are enlarged, with a normal-sized fourth ventricle. An arachnoid cyst is present inferior to the cerebellum.

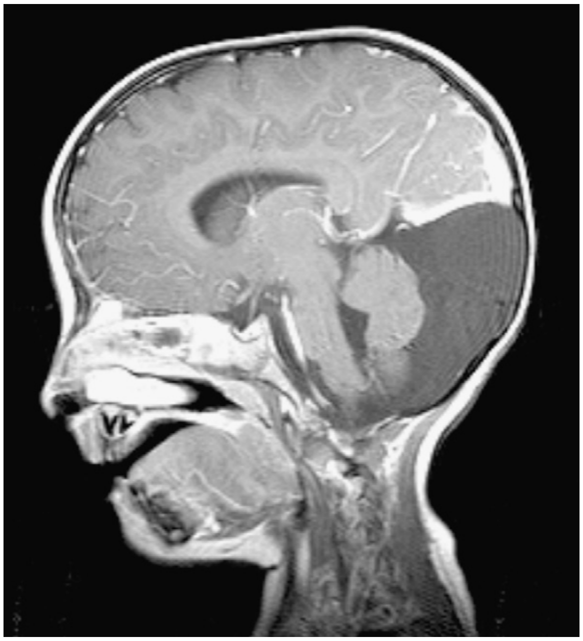

Figure 40–99. Dandy-Walker malformation. T1-weighted sagittal magnetic resonance image shows cystic transformation of the fourth ventricle with enlargement of the posterior fossa, elevation of the torcular herophili, and dysgenesis of the inferior cerebellar vermis.

girls than boys. Infants can present with macrocephaly and an enlarged posterior fossa that precedes the development of hydrocephalus.[37] Mental retardation due to associated supratentorial abnormalities is present in approximately half the cases.[15]

Most children with the Dandy-Walker malformation have hydrocephalus. MRI is useful for demonstrating other anomalies, including agenesis of the corpus callosum, absence of the septum pellucidum, heterotopias, polymicrogyria, aqueductal stenosis, and, occasionally, the presence of an occipital encephalocele or meningocele. Systemic anomalies may include cleft lip and palate, polydactyly, craniofacial malformations, and cardiac abnormalities.[70] The differential diagnosis includes the Dandy-Walker variant, in which the posterior fossa is not enlarged, and the retrocerebellar arachnoid cyst and mega cisterna magna, in which there is no hypoplasia of the cerebellar vermis.

CHIARI II MALFORMATION

See also Part 8.

The *Chiari II malformation*, described in 1896 by Hans Chiari, a pathologist from Prague, is a complex disorder occurring in almost all children with myelomeningocele. Most patients with the Chiari II malformation have hydrocephalus, either from aqueductal stenosis or a block at the outflow of the fourth ventricle, and most require treatment by placement of a diversionary extracranial ventricular shunt. Hydrosyringomyelia may also be present. Multiple associated anomalies affect the skull, dura, and central nervous system. Lückenschädel, or lacunar skull, appears as regions of calvarial thinning that are present in the fetus and usually disappear during the first year of life. The posterior cranial fossa is small with a wide foramen magnum, a low-lying tentorium, and low-lying transverse sinuses. There are often fenestrations in the falx cerebri. The hindbrain is abnormal because of a failure of the embryologic pontine flexure, with herniation of the cerebellar vermis below the foramen magnum and above the tentorial incisura, kinking of the medulla, and elongation of the fourth ventricle. The tectum is beaked and the massa intermedia is enlarged. Enlargement of the occipital horns of the lateral ventricles (colpocephaly) may occur in association with dysgenesis of the corpus callosum. The cerebral hemispheres often contain narrow, elongated gyri (stenogyria) and neuronal heterotopias. The radiographic features of the Chiari II malformation are best detected on MRI (Fig. 40-100), and many features can now be seen accurately on prenatal MRI.

The most obvious clinical manifestation of the Chiari II malformation is the presence of a myelomeningocele. Although hydrocephalus almost always accompanies the Chiari II malformation, the head may not be enlarged at birth. In fact, the head circumference may be small at birth owing to decompression of CSF into the myelomeningocele sac. Approximately 25% of infants with myelomeningocele are born with a head circumference less than the 5th percentile.[52] The head circumference may begin to expand rapidly after closure of the myelomeningocele defect.[70] Other clinical signs in infants with the Chiari II malformation are related to brainstem or cranial nerve dysfunction and include respiratory distress with inspiratory stridor, swallowing difficulties with a depressed gag response, apnea, weak cry, and quadriparesis. Hindbrain dysfunction in the Chiari II malformation may be due to compressive or ischemic factors, but also to dysgenesis of cranial nerve nuclei in the brainstem.

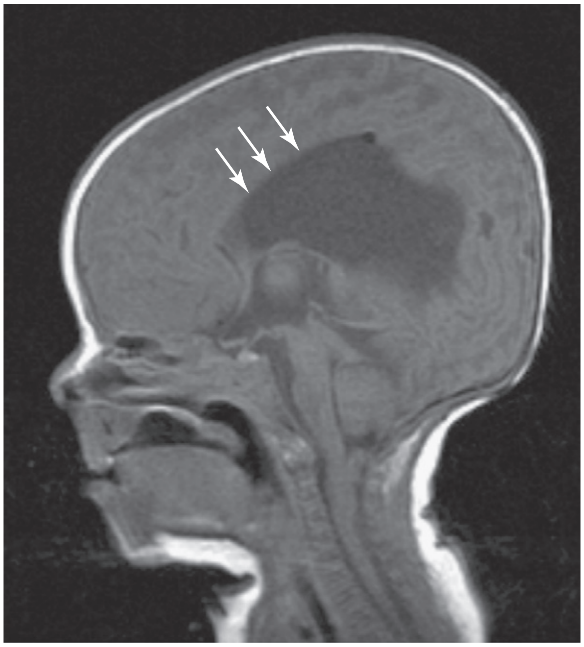

Figure 40–100. Chiari II malformation. T1-weighted sagittal magnetic resonance image shows partial agenesis of the corpus callosum *(arrows)* and multiple anomalies, including enlargement of the massa intermedia, beaking of the tectum, herniation of the cerebellum below the foramen magnum, and kinking of the medulla.

The most frequent cause of brainstem dysfunction in patients with the Chiari II malformation and shunted hydrocephalus is malfunction of the ventricular shunt.

POSTHEMORRHAGIC HYDROCEPHALUS

See also Part 3.

The subependymal periventricular germinal matrix is a site of significant cellular activity during the second and third trimester. Gelatinous in texture, it serves as a focus of neuronal and glial proliferation. The matrix has a rich vascular supply with a complex capillary bed containing large, immature, irregular vessels. After the cellular precursor activity, the germinal matrix undergoes a progressive decrease in size, and by 36 weeks' gestation it is almost completely involuted.[78]

The site of origin of intraventricular hemorrhage (IVH) in neonates is characteristically the subependymal germinal matrix (Fig. 40-101). The significant vascularity, location in the watershed zone, and paucity of vascular supportive tissue make the germinal matrix particularly susceptible to hemorrhage.[33] Neonatal IVH is thought to occur because of fluctuations in cerebral blood flow to the immature germinal matrix vasculature.[60] Because this matrix is largely involuted at term, neonatal IVH is primarily a disorder of the preterm infant. The incidence of IVH in infants weighing less than 1500 g is significant, previously estimated to be approximately 40%,[14,53,58] with most hemorrhages apparent within the first 24 hours of life. Incidence has declined markedly over the last decade (see also Part 3).
